THEORETICAL MECHANICS.

Cours de Mécanique Rationelle et Experimentale, spécialement écrit pour les physiciens et les ingénieurs, conforme au programme du certificat de mécanique rationelle. By Prof. H. Bouasse. Pp. 692. (Paris: Ch. Delagrave, n.d.) Price 20 francs.

A NOTICEABLE feature of this treatise on theoretical mechanics is the large number of practical examples discussed. The majority of these are of a physical rather than an engineering character, some of them dealing with physical apparatus. Investigations of oscillations under various conditions occupy a considerable part of the book. The author claims mechanics as a branch of physics, the first chapter of physics, and aims at supplying a treatise of the kind which is likely to be useful to those whose interest in the subject depends on its applications to practical physical questions. He protests against the unpractical character of the French treatises on the subject written by mathematicians, and of the questions asked in examinations.

To a considerable extent the book fulfils its aim. It contains a great deal of information (including some useful fragments of mathematics connected only incidentally with mechanics), and it is for the most part written in a pleasant, lucid style, slightly marred by occasional eccentricities. As much of the theory is included as is generally needed for practical use, no attempt being made to restrict the use of mathematical methods. There are, however, some slips. An important one, which should puzzle a reader unacquainted with the subject, occurs in the investigation of Euler's equations. Occasionally also the methods adopted are clumsy or unduly ponderous.

A case of ponderous treatment of theory occurs in so simple a matter as the investigation of the composition of angular velocities. The author hints at reasons, not fully explained, which appear to him to make it desirable, "in order to avoid all difficulty," to derive the composition of angular velocities from the study of a succession of finite angular displacements. He goes on to discuss the theory of this at considerable length, a rather tiresome procedure.

Now the meaning of the composition of simultaneous motions is not a very easy thing to understand, and ought to be a matter for clear definition. Without a definition, expressed or implied, it is unintelligible. Prof. Bouasse does not give a definition of it, but he implies that the resultant motion is to be calculated from the limiting case of successive displacements when these are small. Such a method of treatment is not uncommon, but surely the method afforded by the consideration of relative motions taking place simultaneously is preferable. In the case of angular velocities, the mounting of a body in gimbals provides the mechanism which is needed for a clear conception of the composition, the angular velocity of the body being the resultant of its angular velocity relative to an intermediate base and the angular velocity of this base relative to the final one. The difference between the two methods of treatment is not solely one of style. The resultant is given by either method, and an experienced reader would pay no attention to any other feature of the arrangement adopted. But inexperienced readers, for whom the more elementary parts of a book like this must be intended, might reasonably be puzzled by perceiving that successive displacements do not give results identical in all respects with what is proposed. The path of a point of the moving body remains a zigzag up to the limit, and if the length of this path were the thing to be calculated the method of successive displacements would not give a correct result. If the limit of successive displacements is to be regarded as the definition of the composition, it ought to be a correct method for calculating everything about the motion.

It might be expected that a professor of physics, who regards mechanics as a branch of his subject, would give some attention in detail to the physical laws which form the basis of his calculations. Our author, however, frankly ridicules the idea of questioning the truth of them, and does not even take the trouble to state them correctly. He professes to deal with the subject from the beginning, but any reader

who had no previous knowledge of it would be bewildered. No pure mathematician could be more careless as to what the equations which he desires to write down are based upon, or show less interest in the question whether the results to which they lead are verified. Moreover, he does not explicitly refer to the base, relative to which the motions studied are reckoned, according to the theory which he is using, or appear to take any interest in the remarkable fact that the observed motions of bodies define such a base, which presumably has some relation to other physical phenomena. The only occasion on which he attempts to deal with the foundations of the subject is in connection with the law of action and reaction in statics, the treatment of which is clumsy and unconvincing, perhaps even unintelligible.

As in the case of the rest of physics, there are two ways of looking at mechanics, each of which has its own proper place. One is to regard all parts of the subject as coordinated by means of a generalisation which is as comprehensive as possible. The other is to aim rather at isolating the points involved in the subject, so that any degree of independence which they possess may be recognised, and so that it may as much as possible be seen how far the most precisely ascertained results carry us, and whether a doubt cast on any particular doctrine affects the whole foundation of the subject or not. Though the attainment of the former is the constant aim of scientific study, the latter is the proper attitude in which to approach it, and it seems to be a mistake to write the first chapter of physics in a different spirit. W. H. M.

CANNIZZARO'S COURSE OF CHEMICAL PHILOSOPHY.

Sketch of a Course of Chemical Philosophy. By Stanislao Cannizzaro (1858). Alembic Club reprints, No. 18. Pp. iv+55. (Edinburgh: The Alembic Club, 1910.)

THE Alembic Club have done well at this juncture to publish a translation of Cannizzaro's famous letter to De Luca—a letter which, to use Davy's phrase in connection with an equally memorable pronouncement, acted like an alarm-bell on Europe. Indeed, now that he has joined the majority, no more fitting monument to the perspicacity and genius of the great Italian chemist could be conceived than the publication, in the form of an admirably executed translation, of that statement of doctrine which astonished and ultimately convinced the chemical world of the mid-Victorian epoch.

To the chemists of the present age it is hardly possible to convey an idea of the profound sensation which this letter created. The effect was immediate and irresistible. At that time the name of Cannizzaro was hardly known beyond a limited circle of French and Italian men of science. With the appearance of the message came the conviction that a Daniel had come to judgment—that a prophet and a law-giver had arisen amongst us. The middle period of the last century was a time of political ferment and social unrest, and here and there it culminated in revolution. It was equally a period of disturbance and upset in other spheres of human activity than politics and sociology. In chemistry, more perhaps than in the case of any other science at that time, the old order was changing, but the process was destructive rather than constructive. Old faiths were being undermined and thrown down, but the new dogmas had not stability enough to supplant them.

Cannizzaro's letter appeared at what, in the cant-phrase, is termed the psychological moment. It brought order, method, and arrangement into what hitherto had been a mass of inconsistency and contradiction. Its logic was so clear, its appeal to history and to well-ascertained fact so irrefutable, its statement of proof so admirably marshalled, that criticism was silenced, and the doubter disarmed. Before a decade had passed its principles were everywhere accepted, and it is not too much to say that Cannizzaro effected a revolution in chemical thought as momentous in its way as the revolution he was subsequently concerned in bringing about in the political development of Italy.

To the student of chemistry it would be superfluous to enter into an analysis of Cannizzaro's letter, as its principles are now intimately woven into the web of modern chemical doctrine. Indeed, so indissolubly associated is the fundamental basis of Cannizzaro's chemical philosophy with the chemical philosophy of to-day that the statement of these principles, or of the course of argument upon which they are based, would have the semblance of a platitude. But we can assure the student that, however familiar he may be with the outcome of the doctrine with which the name of Cannizzaro will be imperishably connected, he will read with admiration and delight the *pronunciamento* in which the Genoese chemist makes known to his friend and colleague, and through him to the world, the dogma of what was henceforth to be the new chemistry—with admiration for the extraordinary perspicacity and conviction of its argument, and with delight at the simplicity and force of its statement.

T.

PRUNING OF FRUIT TREES.

Fruit Tree Pruning. A Practical Text-book for Fruit-growers working under the Climatic and Economic Conditions prevailing in Temperate Australia. By George Quinn. Pp. vi+230. (Adelaide, Australia: R. E. E. Rogers, Acting Government Printer, 1910.) Price 1*s.* 3*d.*

THE pruning of fruit trees is an operation that demands, on the part of the operator, first, an intimate knowledge of the natural habits of the particular trees, and, in the second place, considerable experience of the general results which follow a proper system of pruning. Unfortunately, every gardener and amateur who cultivates ever so few trees gets the conviction that, come what will, he must prune, and, if he is ignorant of the methods, nevertheless he mutilates the branches and imagines that his trees will respond satisfactorily to the treatment given

them. In these circumstances it is not to be wondered at if the value of pruning in any form or degree has come to be questioned by certain fruit-growers and experimentalists, who have had very little diffi-better to expose all parts of the tree to the sun and of diminishing the crop.

It still remains incontrovertible, however, that young trees are benefited by a moderate degree of pruning if this is carried out by intelligent operators possessing the knowledge and experience necessary for the task. Such pruning is necessary for forming a proper foundation for the tree, for the removal of cross-branches, and the thinning out of the centre in order to better expose all parts of the tree to the sun and air.

This volume, prepared by the horticultural instructor for the Department of Agriculture, South Australia, under the direction of the Hon. Minister of Agriculture, is issued for the purpose of teaching the technique of pruning to fruit-growers having to work under the climatic and economic conditions prevailing in temperate Australia. The author's qualifications for teaching are clearly shown in his sensible and pertinent remarks upon the facts on which the theory of pruning is based, and his description of the objects the pruner seeks to obtain. Having instructed the reader in these matters, he describes the opposite effects of winter and summer pruning, the parts of a tree, and their different values; also the forms of tree to be encouraged, and the best means of developing fruit-bearing wood in place of foliaceous but barren branches. He next passes to a description of the specific treatment of different kinds of fruit, including apricot, plum, cherry, almond, peach, apple, pear, quince, fig, orange, lemon, and loquat.

There are 200 illustrations from photographs, most of these being valuable as a means of explaining the text, but others are inferior, and their omission would not have detracted from the appearance of the volume.

UNCONSCIOUS MEMORY.

Unconscious Memory. By Samuel Butler. New edition. With an Introduction by Prof. Marcus Hartog. Pp. xxxvii+186. (London: A. C. Fifield, Clifford's Inn, E.C., 1910.) Price 5*s*. net.

It is probable that Butler will live in history as the writer of "Erewhon," but his more serious works, dealing with what may be called the philosophical side of biology, are still worth reading, and Mr. Fifield's re-issue will be welcomed by many. The volume under review consists partly of rather personal polemic against Darwin, and partly of a further development of Butler's views as expressed in his "Life and Habit." These views may be summarised as follows.

It is a fact of hourly observation that practice makes things easy which once were difficult (*e.g.*, the playing of a sonata), and even results in their being done without consciousness of effort. It follows that the fact of an intricate action being done unconsciously is an argument for the supposition that it must have been done repeatedly already. Now take the case of a newly-hatched chicken, which pecks at once and perfectly. How is this? It is because something in the chicken remembers having pecked before, and consequently knows how to do it. An individual is not a new being; it—or part of it—has existed in the bodies of its parents. Thus heredity is memory. Cells remember what they have done before, and know how to do it again.

This, followed to its conclusion, involves the attribution of some kind of intelligence even to atoms. Indeed, we can hardly avoid it. Atoms have their likes and dislikes. Carbon and oxygen are sociable, fluorine is reserved and stand-offish. "The distinction between inorganic and organic is arbitrary." (This view is closely akin to that of Haeckel.) All action is purposive and intelligent. When an organism develops a new quality, it is because the organism has felt the need of it. Evolution is therefore teleological from within; differentiation of species, and variations of all kinds, are not entirely due (or as much as Charles Darwin supposed) to natural selection. Here Butler follows Buffon, Lamarck, and Erasmus Darwin.

Mr. G. Bernard Shaw has said that Butler was, in his department, the greatest English writer of the latter half of the nineteenth century; and, though he was only a *dilettante,* it is surprising how illuminating and suggestive his ideas seem, even now, thirty or forty years after first publication. It is noteworthy that Dr. Francis Darwin quoted him with special approbation in his presidential address before the British Association in 1908.

Prof. Marcus Hartog furnishes a useful introduction, discussing Butler's whole work and his place in the history of science.

The first edition of "Unconscious Memory" was reviewed in Nature, January 27, 1881.

THE MAMMALS OF EUROPE.

Faune des Mammifères d'Europe. By Prof E.-L. Trouessart. Pp. xvii+266. (Berlin: R. Friedländer and Sohn, 1910.) Price 12 marks.

In issuing an up-to-date descriptive catalogue of the mammals of Europe Prof. Trouessart has conferred a real and lasting benefit on zoological science, since, owing to the great increase of species and races due to modern methods of discrimination, the well-known work of Blasius has long been practically useless. Indeed, if the two works be compared, it might at first sight be difficult to believe that they treat of the same subject, so great has been the increase in the last few years in the number of recognisably distinct forms, and so extensive the changes in nomenclature. Nowadays views differ—and will probably continue to differ—as to the limitations of species and races; but Dr. Trouessart appears inclined in most cases to use the former term in the most restricted sense. Justifying himself in doubtful instances by the dictum of Desmarest that "il est plus misable de trop réunir que de trop diviser," he might, if we remember rightly, have supported an opposite view by a statement of Huxley to the effect that it is more important to re-

cognise resemblances than to overlook differences; and in the excessive multiplication of genera and species (as distinct from division into races) there is undoubtedly a great danger of losing sight of mutual affinities.

As instances of this multiplication, reference may be made to the specific separation of the Irish from the Scotch hare, of the Scotch from the English wild cat, and of the British from the Continental water-rats. On the other hand, the British squirrel is regarded merely as a local race of the Continental species, a classification difficult to reconcile with that adopted in the case of the species just mentioned. Whatever may be individual views on such matters, we venture to think that most naturalists will agree in objecting to the principle of introducing the names of one or more species between those of the typical form and the races of another, as is done in the case of the wild cats. In regard to generic grouping, it may be mentioned that, in the case of mice, the long-tailed species appears as *Mus sylvaticus*, and the harvest-mouse as *Apodemus minutus*, whereas the latter (if generic splitting be adopted), should be *Micromys minutus*, and the former *Apodemus sylvaticus*. The weasels, again, are included in the same genus as the polecats, from which they are sundered by many modern naturalists. As regards the distribution of the European fauna, the author recognises four distinct areas, viz., Central European, Arctic, Eastern or Steppe, and African or Mediterranean.

While congratulating Dr. Trouessart on the completion of a laborious task, we may take the opportunity of mentioning that his work strongly emphasises and confirms a reply the present writer was compelled to make some months ago to Dr. A. R. Wallace, namely, that to give, even approximately, the number of species of mammals inhabiting the various zoological provinces is, under present conditions, an absolute impossibility. It is very largely a case of "go as you please." R. L.

THE SCIENCE OF PATHOLOGY.

The Principles of Pathology. By Prof. J. G. Adami, F.R.S., and Prof. A. G. Nicholls, F.R.S. (Can.). Vol. II., Systemic Pathology. Pp. xvi+1082. London: Henry Frowde and Hodder and Stoughton, 1910.) Price 30s. net.

THIS second volume of Prof. Adami's great work on the science of pathology deals with systemic pathology—the pathology of the individual tissues and organs of the body, or special pathology, as it is often termed—and has been written in conjunction with his colleague, Prof. Nicholls. In the preface the authors offer an (unneeded) apology for the bulkiness of the first volume on general pathology (reviewed in NATURE of November 25, 1909, vol. lxxxii., p. 94), and the relative brevity of this second volume, for many would consider that special pathology requires at least double the space devoted to general pathology. They point out, however, that, provided the student has acquired a good grasp of general pathology, he has but to apply those principles in order to become possessed of a sound basis of special pathology, a proposition with which we are in complete agreement.

But for the inclusion, therefore, of the pathology of the blood and cardio-vascular system, and also of the disorders of function as well as of structure of the various organs, even the present volume might have been curtailed in length. At the same time, we think that this attempt at brevity has in some cases been carried too far, and although the subjects may have been dealt with at length in the first volume on general pathology, some repetition would not have been out of place. As instances, we may mention the bare reference to diabetes in the section dealing with the pancreas, and the omission of blackwater fever as a disease in which hæmoglobinuria occurs. Otherwise, we confess we have found little to criticise, and the work gives a very full and accurate account of the subject.

Each organ is dealt with on a systematic plan; first a brief summary of its developmental history, anatomical structure and physiological functions, followed by a description of the congenital and acquired abnormalities, circulatory disturbances, inflammations and parasitic infections, and retrogressive and progressive metamorphoses to which it may be subject. In the division devoted to the blood and cardio-vascular system, the sections dealing with leukæmia seem somewhat brief in view of the importance of the subject, and no mention is made of cases of the lymphatic variety in which the total number of leucocytes is not markedly increased, but in which nearly all the leucocytes present are lymphocytes. In the section dealing with pernicious anæmia also no mention is made of the almost invariable leucopenia present, a point of considerable diagnostic importance in the numerous cases in which the blood picture is not typical. In discussing the origin of œdema, the authors hold that the facts demand the assumption (with Heidenhain) that the lymphatic and capillary endothelium is endowed with a certain grade of selective secretory activity.

In the section dealing with the diseases of the nose it is surely not expedient to refer to the common polypus as a "polyp," a term which now has a more or less definite zoological signification.

We congratulate the authors heartily on the completion of their labours; the work is not a mere compilation, but is the outcome of a ripe personal knowledge of the subject. Divergent views are stated fairly, and if the authors' views do not always agree with those current, the reasons are given, and they merit careful consideration.

The book is profusely illustrated with plates and figures (some coloured), drawn or photographed directly from patients, specimens, and sections, which are admirably reproduced. We think it a mistake, however, not to have given the magnification of the photomicrographs; simply to state, as is done, the lenses with which the photographs were taken does not sufficiently indicate the magnification of the object depicted.

OUR BOOK SHELF.

Household Foes. A Book for Boys and Girls. By Alice Ravenhill. Pp. xxiii+359. (London: Sidgwick and Jackson, Ltd., 1910.) Price 2s. 6d.

MISS RAVENHILL has written this small work with the object of arousing the interests of boys and girls in the practice of daily domestic cleanliness, and at the same time of furnishing them with reasons for this practice. She also aims at indicating the links which should be made to connect school lessons with home habits, and prominence is given to the value of good habits and to the necessity for their constant daily practice. She directs attention to the broad educational value of the subject of "hygiene," in exercising observation and reason, and in cultivating the habit of tracing effects to their causes. The text of most of the chapters is "dirt"—the dirt of home surroundings, of air, water, and food; and at the end of each chapter references are given to works in which the subject-matter may be further studied and developed, more especially on the practical and experimental side. Young people are slow to learn that there are no rights apart from responsibilities, which in this connection include duties to self, to home, to community, to empire, and to race; it is well, therefore, that Miss Ravenhill devotes her two concluding chapters to "the citizen's power to control dirt, decay, and disease," and "imperial safeguards against dirt and disease."

Hygiene has gradually found a footing in the elementary school code; but one cannot hope, for some years to come, to get the best results of this teaching and training, for the reason that school teachers as a body do not possess the necessary knowledge to enable them to present the subject with judgment and discrimination. This small work well serves as a very useful guide to them, and to this end it is perhaps the best statement hitherto published, for the essential facts are dealt with in an appropriate and impressive manner, and the book contains little (if anything) which is unsuitable or unnecessary, while the authoress tells practically all that it is necessary to tell. A child with the elementary knowledge of hygiene which Miss Ravenhill seeks to convey, and trained to act in accordance with its precepts, should be well equipped from the standpoint of hygiene. The book may be confidently recommended to all those parents and teachers who are concerned with the education of the young.

History of Chemistry. By Sir Edward Thorpe, C.B., F.R.S. Vol. i., From the Earliest Times to the Middle of the Nineteenth Century. Pp. viii+148. Vol. ii., From 1850 to 1910. Pp. viii+152. (Issued for the Rationalist Press Association, Ltd.) (London: Watts and Co., 1909 and 1910.) Price 1s. net each volume.

SIR EDWARD THORPE, who has enriched chemical literature with so many valuable biographical contributions, has added greatly to our indebtedness by the publication of these two small volumes of chemical history. In method and style they follow the eminently readable work of Thomas Thomson, which has been so long out of print, and in many respects out of date, and the modern student is now supplied with a brief history of chemistry, which is well within his intellectual and material means, and cannot fail to add greatly to the interest of his studies. The divorce of historical and other human interest from the study of science, resulting from our examination system, is greatly to be deplored. It gives good ground for the allegations of aridity so often made against scientific teaching and scientific text-books, and it deprives the student of much that would aid him in the comprehension of modern chemical theory. It is to be hoped that these volumes will have a very wide circulation, and that students may be encouraged to proceed to study some of the works which are indicated in the appended bibliographies.

The first volume, beginning with the chemistry of the ancients, brings the reader to the early part of the nineteenth century, whilst the second volume follows the subject to the present day. This last volume is naturally highly compressed, but, like the first, it bears the imprint of a master-hand in the exact and readable presentation of chemical history. A series of admirable portraits is inserted throughout the work. A. S.

A Course of Elementary Science, Practical and Descriptive. By John Thornton. Pp. vi+216. (London: Longmans and Co., 1910.) Price 2s.

THIS book, which contains chapters on measurement, mechanics, and heat, is intended by the author for junior pupils who are attending class and laboratory instruction. As the title implies, it is partly descriptive and partly practical in character. After perusing the book one is led to the conclusion that the author has not a very wide acquaintance with physics or much experience of up-to-date laboratory methods. The book has the characteristic of those many manuals on this subject which appeared so hurriedly ten or twelve years ago. The language is often loose, *e.g.* p. 13, Expt. 1, "Draw a large circle on a sheet of cardboard and divide it into degrees." On p. 29 the author states that results need not be carried beyond the second decimal place as a rule. In determining quantities in the laboratory where the final result is obtained by arithmetical operations on quantities actually measured, it is the degree of accuracy with which these several quantities are measured that determines the number of significant figures in the final answer. Such examples as Expt. 11, p. 35:—Weight of lead in air, 17 oz.; weight of lead in water, $15\frac{1}{2}$ oz.; specific gravity, 11·3; or the example on p. 41:—3000/0·85=3529·4 c.c., are ill-chosen. On p. 131 we are told that the steel rails of a tram line have a small space left between their ends, when laid, to allow for expansion. How many observant boys have looked for such spaces and failed to find them? On p. 144 it is stated that water expands regularly from ordinary air temperature to 100° C.

The Brooks Patent T-square Lock. (Letchworth, Herts: Wm. J. Brooks and Co.) Prices 4s. 6d. and 5s. 6d.

THIS very useful adjunct to the ordinary T-square is one of the best of the devices which have recently been introduced to facilitate the work of the draughtsman, and it will be much appreciated by all who are engaged in mechanical and architectural drawing. The contrivance is simple in character, moderate in price, and well made, and is designed so as to be readily attachable to any existing square, no alteration of the drawing board being required. By its use the T-square, without loss of freedom, is instantly locked in any desired position on the board, thus freeing both the hands of the operator. The lock may be put out of action at will, and the T-square manipulated in the ordinary manner. The "lock" attachment will be found extremely serviceable when used with a board which rests horizontally, as on a table, but when the board is much inclined or is vertical, the employment of this or a similar device is indispensable. There are many teachers who might with great advantage utilise this apparatus for black board work.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Helium and Geological Time.

IN NATURE of October 27 (p. 543) a short notice appears relative to some experiments of Prof. A. Piutti, of Naples, on the occlusion of helium from the air by salts in the act of solidification. Prof. Piutti apparently considers his results as throwing doubt on the figures which I have given for the age of different geological formations from the accumulation of helium in them. I wish to give my reasons for dissenting from this criticism.

In the first place, it is not clear from Prof. Piutti's description that the gases extracted from his solidified salts contain any more helium than normal atmospheric air. He has not attempted to show, if I understand his description rightly, that there is any *selective* absorption of helium in preference to the other atmospheric gases; nor is it at all likely that such a selective absorption exists, for we have no knowledge of chemical affinity between helium and other gases, while, in respect of solubility, it would probably be inferior to them. Again, on account of its low molecular weight, it would, if anything, be better able to escape from mechanical retention. But the gases from minerals are in practically all cases many times richer in helium than is atmospheric air. Mere retention of air cannot therefore account for any appreciable proportion of the helium found.

There remains the question, also alluded to by Prof. Piutti, of whether helium can have been absorbed from any source in the interior of the earth. I have already discussed this question, as regards igneous rocks, in Proc. Roy. Soc., A, vol. lxxxiii., p. 298. As regards the bulk of the rock, it is impossible to exclude such an origin, and I have carefully avoided drawing conclusions which might be vitiated by it. My inferences have been drawn from minerals like zircon and sphene, which are immensely more radio-active than the rock in general, and immensely richer in helium. It is without plausibility to assume that the excess of helium in these has any extraneous origin.

Pwdre Ser.

ON my return from a field season beyond the reach of periodicals, I have just seen, for the first time, Prof. McKenny Hughes's article on "Pwdre Ser" in NATURE of June 23, and the correspondence relating thereto in the succeeding numbers. It may interest your readers to know that a substance of this sort was found by Mr. Rufus Graves (at one time lecturer on chemistry in Dartmouth College) at Amherst, Mass., on August 14, 1819, and by him identified with a luminous meteor which had been seen to fall at that spot on the previous evening. His report of the occurrence appeared in the *American Journal of Science*, vol. ii., pp. 335–7, 1820. The mass of jelly was circular, about 8 inches in diameter and about 1 inch thick. It was of a bright buff colour, and covered with a "fine nap similar to that on milled cloth." The interior was soft, of an insufferable odour, and liquefied on exposure to the air. Some of this liquid was allowed to stand in an open glass for a few days, when it had entirely evaporated, leaving only a small quantity of a "fine ash-coloured powder without taste or smell," which effervesced strongly with sulphuric acid, but not with nitric nor hydrochloric.

Mr. Graves's account was noted by Arago in the *Annal. de Chimie*, vol. xix., pp. 67–9 (1821), who quoted also several similar occurrences cited in earlier chronicles. It is probable, of course, that Mr. Graves was mistaken in his identification, that the meteor actually fell at some other point, and that the jelly was confused therewith only because no other unusual substance was found at the point where the meteor was *supposed* to have fallen. Mr. Graves himself considered that there was "no reasonable doubt that the substance found was the residuum of the meteoric body," but the evidence which he states is hardly satisfactory to the modern, more critical inquirer.

It seems probable that these jellies are, in general, plasmodia of some form or forms of Myxomycetes, and that their common identification with falling stars may have its basis in the frequent recurrence of this error into which Mr. Graves seems to have been led. It is well known that visual estimates of the distance of falling stars are almost invariably far too low. If, then, an untrained observer of a meteor goes next morning to the near-by place where he *thought* he saw the body fall, and finds there no unusual body excepting one of these plasmodia, the jelly and the meteor are almost sure to be associated in his mind. Especially is this probable, since the plasmodia, in general (at least in my experience), have the appearance of having fallen on the grass rather than of having grown there.

On Hydrogen in Iron.

AT the recent meeting of the British Association at Sheffield, Sir Norman Lockyer referred to the relationship between hydrogen and iron at stellar temperatures. Some observations of mine, made several years ago, are of interest in this connection. I also note that at the recent meeting of the Iron and Steel Institute, in a discussion on the influence of carbon in iron, it was suggested that the gases known to be present should also receive attention.

Iron contains ten times its volume of hydrogen, and in many instances 20 volumes of hydrogen; even 100 has been noted. Iron therefore contains from about 0·013 to 0·026 per cent. of hydrogen, 100 volumes equalling 0·13 per cent., all deemed important in metal with like proportions of carbon and sulphur and phosphorus. It is now fully admitted that hydrogen hardens iron, and should therefore be estimated: 1 gram frozen H, *ice* = 7·2 c.c., 0·1 = 0·72 c.c. I note also iron = 1 c.c. = 7·2 gram iron. 1111 c.c. of solid H = 1/10 gram in 100 iron = 14·4 c.c. = 7 grams per 1000 c.c., and 1000 ordinary pressure = only 0·08961 gram. The figures quoted are apparently in accordance with the periodic law, series 1–7.

As regards the above, more might be said if space permitted.

October 19.

Research Defence Society.

IN connection with the cases of plague in Suffolk, let me say that this society has lately published an illustrated pamphlet on "Plague in India, Past and Present," by Lieut.-Colonel Bannerman, director of the Bombay Bacteriological Laboratory. It gives a full account of the experiments which proved that fleas carry the plague from rats to man; it also gives a full account of Haffkine's preventive treatment, and of the many thousands of lives which have been saved by this treatment. I am sorry that the Research Defence Society cannot afford to give away this pamphlet in large quantities, but I shall be happy to send it to any of your readers who will send me seven stamps. I shall also be happy to send copies, on sale or return, to all booksellers.

STEPHEN PAGET.

(Hon. Secretary Research Defence Society.)

21 Ladbroke Square, London, W.

British Mammals.

I AM grateful for your reviewer's good wishes for the success of my book (NATURE, October 20). He writes that he has only one fault to find, namely, that a paper of Dr. K. Andersen's dealing with the authority for the names *Nyctalus noctula* and *N. leisleri* is not mentioned anywhere. I beg to state that the title of this paper is given on p. 53. It could not be cited in the synonymy, as the names *Nyctalus noctula* and *N. leisleri* do not actually occur in it. In fact, I believe that my book is the first in which these names occur.

G. E. H. BARRETT-HAMILTON.

THE OCEANOGRAPHICAL MUSEUM AT MONACO.

IN the history of the development of the study of the sea all the sciences find an application, and all were worthily represented at the inauguration of the Oceanographical Museum of Monaco on March 29 of this year. The ceremonies and festivities incident to the occasion have already been chronicled in the columns of NATURE (April 14, vol. lxxxiii., p. 191). It is proposed here to give an impression of the life-work of the Prince of Monaco, which found expression in the solemnities of that occasion. The accompanying illustrations[1] afford an idea of the magnificence of the building and of the richness of the collections. Fig. 1 gives a view of the museum from the sea. The scale on which it is built can be judged from the fact that the height of the roof above the lowest masonry is 75 metres. Fig. 2 is the statue of the Prince standing on the bridge of his yacht. It is an artistic work, and a good portrait. It gives fine expression to the modesty as well as to the power of the creator of the great monument in the centre of which it stands.

The museum and the vessels attached to it, with their staffs and general organisation, are only one-half of the great enterprise which is entitled, "Institut Oceanographique Fondation Albert Ier Prince de Monaco." Its seat is in Paris, where it possesses its own buildings and a rich endowment, both of them the gift of the Prince. It has professors of physical and biological oceanography and of the physiology of marine animals, and the lectures delivered during last year had the most numerous attendance of any in Paris. During the life of the Prince he exercises supreme authority. Both in Paris and at Monaco there is complete organisation for giving effect to his wishes, and, in the event of his death, for carrying on the work without interruption, and on the lines inaugurated by himself. Thus continuity and permanence have been assured.

It will be readily realised that the establishment of these two great institutions has not been accomplished without the expenditure of large sums of money and the devotion of much time and labour to it. It is almost impossible for anyone to realise the greatness of the work which is being accomplished without having been intimately connected with it, and even with this advantage the development of the conception is slow. As with all great achievements, it will take at least a generation before it is thoroughly understood and adequately appreciated.

The museum at Monaco bears testimony at every turn to the great lines on which the Prince has himself worked, and in which his work is fundamental. Thus, in the purely hydrographical department, we see his bathymetrical chart of the world, on which all the trustworthy deep soundings are entered. This great document may be said to be the foundation-stone of oceanographical work. Another and much earlier piece of hydrographical work is the current chart of the North Atlantic, which gives the result of his laborious work on board the *Hirondelle*. By the methodical dispersion of floats, especially constructed to expose the least possible surface above water, along different lines radiating generally from the group of the Azores, by patiently awaiting their recovery, and by then combining their records, he furnished the demonstration that this portion of the ocean is practically a lake, bounded, not by land, but by the motion of its own peripheral waters, thus enclosing a roughly circular portion of the sea, part of which is generally associated with the Sargassum weed and called the Sargasso Sea. The water, thus self-confined in the warm, dry subtropical region, is exposed to powerful evaporation, and to a considerable annual variation of temperature at the surface. The combination of these two thermal factors furnishes the mechanical power by which the deeper layers of the water obtain more heat and attain a greater density in this sea than they do in any other part of the open ocean, as was pointed out by the writer in a paper "on the vertical distribution of temperature in the ocean," read before the Royal Society on December 17, 1874, and published in its Proceedings, vol. xxiii., p. 123.

FIG. 1.—General view of the Oceanographical Musenm at Monaco as seen from the sea.

In the great hall to the left of the entrance the visitor is at once struck by the magnificent collection of skeletons of Cetaceans, which includes those of many species. These are skeletons of individual whales, nearly all of which have been killed by the Prince himself, and each is complete, every bone in the animal being accounted for. From all points of view this collection is at once the most attractive and the most interesting in the museum, and in it we see the Prince reflected as a hunter and as a naturalist.

In Fig. 3 we have the Orca, with its formidable double row of teeth. It preys on other Cetaceans, and always shows plenty of sport. The specimen figured belonged to the leader of a school of three, which was

[1] For the illustrations in this article we are indebted to the courtesy of the proprietor of the *Naturwissenschaftliche Wochenschrift*. They are reproduced from photographs by Prof. Doflein, of Munich, and illustrate an article by him in that periodical.—Editor, NATURE.

met with a few miles outside of Monaco. They fought to the death, and when killed they were towed in and beached on what is now the new harbour of Monaco.

FIG. 2.—Statue of Prince Albert I. of Monaco in the Museum

Not far from the Orca is a skeleton, Fig. 4, of the best known of the toothed Cetaceans, the cachalot or sperm-whale. It was not taken by the Prince himself, but he was present at its capture, and his scientific instinct enabled him to seize an opportunity which would probably have been missed by another. The cachalot had been struck by a crew of whalers from Terceira, one of the islands of the Azores. The Prince followed the chase in his yacht, and was close to the animal when it became evident that its end had come. At this moment these animals always charge whatever they see, and in their death agony they usually render whatever they have last eaten. This animal charged the *Princesse Alice*, but the charge did not get home. The animal stopped, and a large mass of something came out of its mouth close to the yacht and began slowly to sink. The Prince at once jumped into the dinghey, and, with a long landing net, retrieved the object before it sank out of sight. The object is represented in Fig. 5, and is a unique piece. It is a fragment of the gigantic scaled cephalopod which Prof. Joubin, who described it, named *Lepidoteuthis Grimaldii*.

A healthy cachalot is valued for the spermaceti, or wax, which is contained in its head, and a sick one is still more valued for the ambergris which it may contain. This curious substance, which has at all times been so highly esteemed in pharmacy and perfumery, forms the subject of a very interesting "Account of Ambergris" by Dr. Schweidawer, which was read before the Royal Society on February 13, 1783, and published in the Philosophical Transactions, vol. lxxiii., p. 220. From his investigations it appears that ambergris is a by-product of an inflammation of the intestine, which has probably been started by the "beaks" of the cephalopods which it has swallowed, for these are the invariable and characteristic ingredient of all genuine ambergris. He further states that the whalers are convinced that the cachalot feeds only on squids, which, when unmutilated, must be of great size. One whaler reported a case where the whale in its death-throe rendered a single tentacle, which, though incomplete from having been partially digested, still measured 29 feet in length, and he held that this justifies the common saying of the whalers that the squids are the biggest fish in the sea.

The work of the Prince amongst the toothed Cetaceans has had an interesting sentimental result. The combat of the "thrasher" and the whale, so dear to the nautical mind, seems to be

FIG. 3.—Skeleton of the great Orca killed by the Prince of Monaco near Monaco.

nothing but the violent and desperate resistance of the giant squid to being swallowed when brought to the surface by the cachalot.

The whalebone whale, shown in Fig. 6, was struck by the Prince in May, 1896, not many miles from Monaco, but it escaped. Its carcase was washed ashore in September of the same year, near Pietra Ligure, on the Italian Riviera. A remarkable feature of this skeleton is the evidence of fracture and repair of a number of ribs of its left side. This has been ascribed to collision with a steamer, but it is very unlikely that such an experience would leave its mark in nothing but a number of perfectly repaired ribs. It would seem to point to a type of accident to which whales are certainly exposed, and from which they perhaps not infrequently suffer.

FIG. 4.—Skeleton of the Cachalot which furnished the fragments of gigantic Cephalopods

The habitat of the whale is the air and the water, and its functional economy has to be adapted to life in both elements, or rather, to life sometimes in the one, at other times in the other element.

In one of the Prince's recent cruises in the Mediterranean the yacht was found to be steaming in the wake of a whale, which was evidently making a passage, and in a leisurely way. The Prince seized the opportunity to follow the animal without pursuing it, and this was done with such skill that it remained unconscious of being followed. It kept a steady course, and, to "keep station" with it, the *Princesse Alice* had to steam at a speed of about ten knots. In these conditions the whale came up to breathe at regular intervals of between ten and eleven minutes, the intervals between the spouts being the same almost to a second. This experiment supplies an important constant in the natural history of the whale. It looks very simple, but it will not be readily repeated, except perhaps by the Prince himself. As the whale was on passage, it is unlikely that it went far below the surface, but there is abundant evidence that, in the search for food or to escape enemies, it penetrates to very considerable depths. In these excursions its body is exposed to rapid and considerable variations of pressure. These have to be borne by the structural frame of the animal, of which the ribs are an important part.

It is generally assumed that, before sounding, the whale fills its lungs with air, but this, being at atmospheric pressure, is of no use in assisting the body to resist the external pressure of a column of water equivalent, it may be, to many atmospheres. How the power of resistance is, in fact, provided, I am not anatomist enough to know, but it must be finite, and it is easy to imagine conditions in which the animal, whether in the pursuit of prey or in the endeavour to escape being made itself a prey, may strain it beyond its limits, and the ribs of one side, whichever is the weaker, may give way. In such an accident, beyond being broken, the ribs need not be seriously disturbed, and with the return to the surface or more moderate depths, they would fall into their places again, and that all the more easily because there is little or no pressure of one part on another, every part of the body of a totally immersed animal being

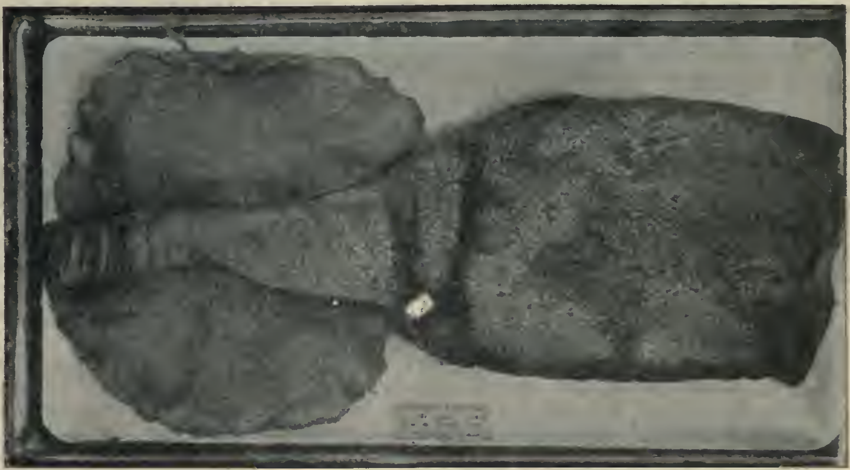

FIG. 5.—The principal ragments of *Lepidoteuthis Grimaldii*, Joubi

water-borne. In such conditions recovery would be rapid and the joints perfect, as can be seen to be the case in the skeleton in the museum.

The accident to this whale is very suggestive. In a well-known experiment, Paul Bert reduced the pressure of the air in the lungs of a dog by a not very large fraction of an atmosphere, when the thorax immediately collapsed, every rib being broken. When a whale is struck and sounds, if only to a depth of one hundred metres, the pressure on its body is increased tenfold in a few seconds. How does its body stand it?

It is certain that the cachalot finds its prey in water of considerable depth. When it has seized it, can it swallow it *in situ*, in a medium of water under very high pressure? The dentition of this animal, a formidable row of teeth in the lower jaw fitting into corresponding sockets in the upper jaw, makes it certain that, when it has seized its prey it can hold it indefinitely. It has been observed that the cachalot sometimes takes its prey to the surface and swallows it there. Is this accidental or habitual? If habitual is it not another link with the far-back time when its habitat was the air and the land? These are some questions suggested by an attentive visit to the Museum of Monaco.

In the museum, room is provided for a department of meteorology, a science which, especially as regards its application to the higher regions of the atmosphere, owes much to the participation of the Prince in its development. Until he directed his attention to it, the *ballons-sonde*, carrying their freight of valuable instruments, were very frequently lost. Now, thanks to the method of keeping the "dead reckoning" of the balloon, developed and brought to perfection on the *Princesse Alice*, if it is followed for a few minutes during its ascent, it may disappear in the clouds, and its recovery, when it descends at sea, is almost a certainty. This department of investigation has been prosecuted outside the Mediterranean, and in the Prince's cruises of the last two or three years it has been carried from the Cape Verde Islands in the heart of the tropics to the north of Spitsbergen, within five hundred miles of the Pole.

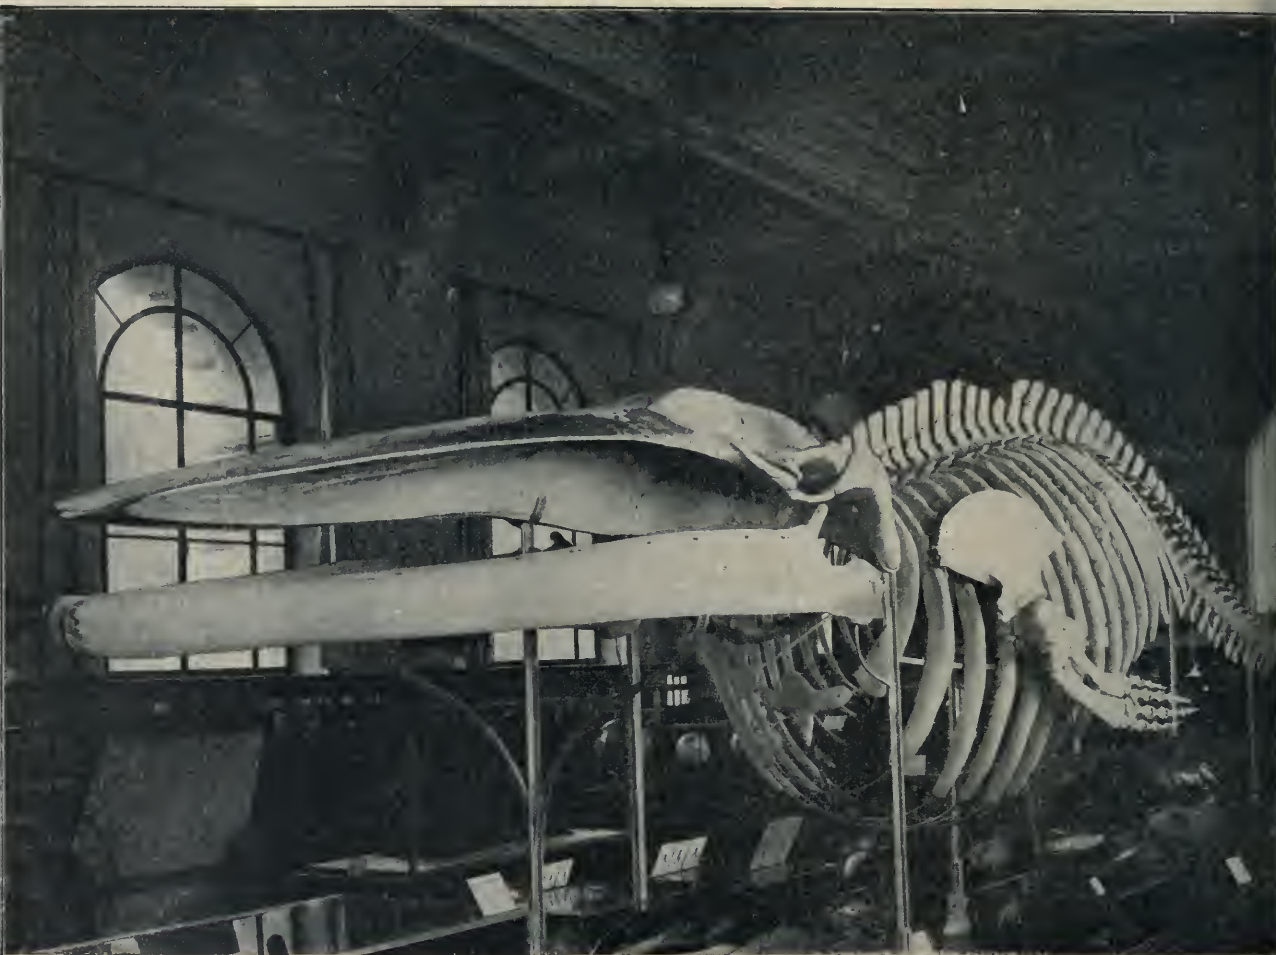

FIG. 6.—Skeleton of whalebone whale the ribs of which have been broken and mended.

Besides the collections of animals and the instruments for their capture and study, there is in the lower part of the museum an aquarium, remarkable for its size and the completeness of its installation. This already commands a constant flux of visitors, chiefly the curious, but it is also frequented by men of science for serious study. It is already proposed to enlarge it considerably. The storey above the aquarium is divided into separate laboratories, fitted

with a service of both fresh and sea water, and everything else required for chemical, physical, and biological study. In these laboratories the occupant has all that a laboratory can supply, and at any time fresh material from the sea, collected by one of the small steam tenders of the museum.

Any notice of the museum of Monaco would be incomplete without an acknowledgment of what it owes to its director, Dr. Richard. None of the many men of science who have enjoyed the hospitality, either of the museum or the yacht, will require to be reminded of this, nor will they forget what they individually owe to Dr. Richard's never-failing courtesy and helpful aid. Personally, I have more thanks to offer than I can express for the countless services that he has rendered me during our friendship of twenty years. The Prince was fortunate in being able to attach him to his service in the early days of the *Hirondelle*. Since that time Dr. Richard has been his never-failing aid and assistant. It is not too much to say that without Dr. Richard's strenuous and unselfish work during these many years the museum with its rich collections and complete equipment would not be, as it is now, the greatest institution of the kind in the world.

J. Y. BUCHANAN.

ENVIRONMENT VERSUS HEREDITY.[1]

THE question of the assimilation of immigrants under American conditions has long been looked upon as of vital importance, and it has been much discussed, but heretofore with little accurate information. Speaking from general personal observation, people have thought that under the influence of the existing educational, social, and political conditions the immigrants gradually change their habits of life and their ways of thinking, and thus become Americans. The statement is often made that American citizens tend to resemble the American Indian, meaning thereby some generalised type of plains Indian, but this has never been put to scientific test. Little or no thought, however, has been given to the possible effect of the physical and social environment on the physical type of descendants of immigrants. The establishment by Congress of the Immigration Commission in February, 1907, gave the opportunity for a thorough investigation of the problems of immigration, and the inquiry into the anatomical characters of immigrants and their descendants was put under the direction of Prof. Franz Boas, of Columbia University, than whom no better selection could have been made. The present short report deals with only a portion of the material collected, but results obtained are of unexpected interest and importance.

The results so far worked out may be summarised as follows:—

1. The head form, which has always been considered as one of the most stable and permanent characteristics of human races, undergoes far-reaching changes due to the transfer of the races of Europe to American soil. The East European Hebrew, who has a very round head, becomes more long-headed; the south Italian, who in Italy has an exceedingly long head, becomes more short-headed; so that both approach a uniform type so far as the roundness of the head is concerned. Fig. 1 shows at 1 and 1 the cephalic index of foreign-born Hebrews and Sicilians; at 2 and 2 that of those born within ten years after the arrival of their mothers in the United States; at 3 and 3 that of those born more than ten years after the arrival of their mothers in the United States. The diagram shows the very rapid approach of the two types among children born shortly after the arrival of their mothers in America, and the slower continuation of this approach among those born later. Fig. 2 roughly indicates the general form of (1) the foreign-born Hebrew, (2) the foreign-born Sicilian, and (3) the average form of the head of the American-born Hebrew and Sicilian-born more than ten years after the arrival of the mother in America.

2. The influence of American environment upon the descendants of immigrants increases with the time that the immigrants have lived in the country before the birth of children.

3. The changes in head form consist in the increase of some measurements and in the decrease of others. The length of the head of Hebrews is increased; the width of the head and the width of the face are decreased. Among the Sicilians the length of the head is decreased, the width increased, but the width of the face is decreased.

4. The differences in type between the American-born descendant of the immigrant and the European-born immigrant develop in early childhood and persist throughout life.

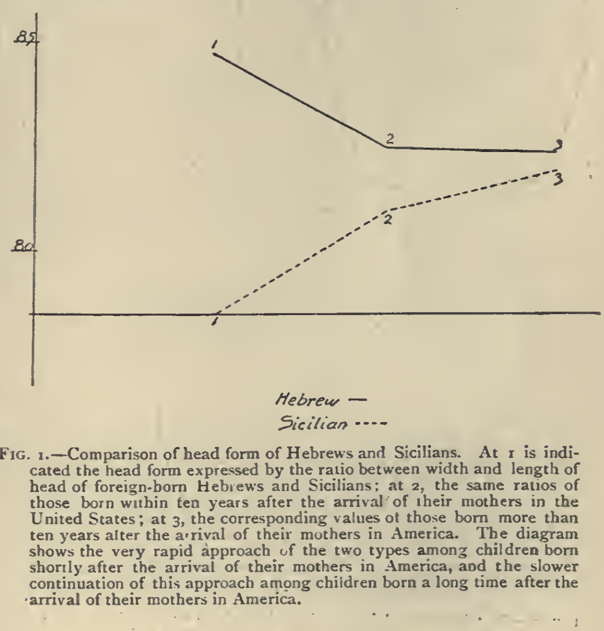

FIG. 1.—Comparison of head form of Hebrews and Sicilians. At 1 is indicated the head form expressed by the ratio between width and length of head of foreign-born Hebrews and Sicilians; at 2, the same ratios of those born within ten years after the arrival of their mothers in the United States; at 3, the corresponding values of those born more than ten years after the arrival of their mothers in America. The diagram shows the very rapid approach of the two types among children born shortly after the arrival of their mothers in America, and the slower continuation of this approach among children born a long time after the arrival of their mothers in America.

5. Among the East European Hebrews the environment, even in the congested parts of the city, has brought about a general more favourable development of the race, which is expressed in the increased height of body (stature) and weight of the children. The Italian children, on the other hand, show no such favourable influence of American environment, but rather a small loss in vigour as compared to the average condition of the immigrant children; so that it appears that the south Italian race suffers under the influence of American city life, while the East European Hebrew develops under these conditions better than he does in his native country.

6. The type of the immigrant changes from year to year, owing to a selection which is dependent upon the economic conditions of the country. This is shown by the fact that after the panic of 1893 a sudden decrease in the general development of immigrants may be observed, which persisted for several years. A similar change seems to have taken place

[1] "Changes in Bodily Form of Descendants of Immigrants." The Immigration Committee, Document No. 208 presented to the 61st Congress, 2nd Session. (Washington, D.C., U.S.A., 1910.)

after the panic of 1907. The significance of these changes is at present obscure.

7. It has been observed that, while immigrants have large families, the size of the family is very materially reduced in the second generation. This reduction of the size of the family goes hand in hand with the improvement of the physical development of the individual, as is demonstrated by the fact that children belonging to small families are considerably taller than children belonging to large families.

In connection with this last statement it is worth noticing that Prof. Boas points out that statistics taken on the school children of Toronto, Ont., and Oakland, Cal., show that there is a decided decrease in development of the individuals according to the increasing size of the family, and the Toronto material proves that the decrease in stature with increasing size of family takes place on every economic level. This

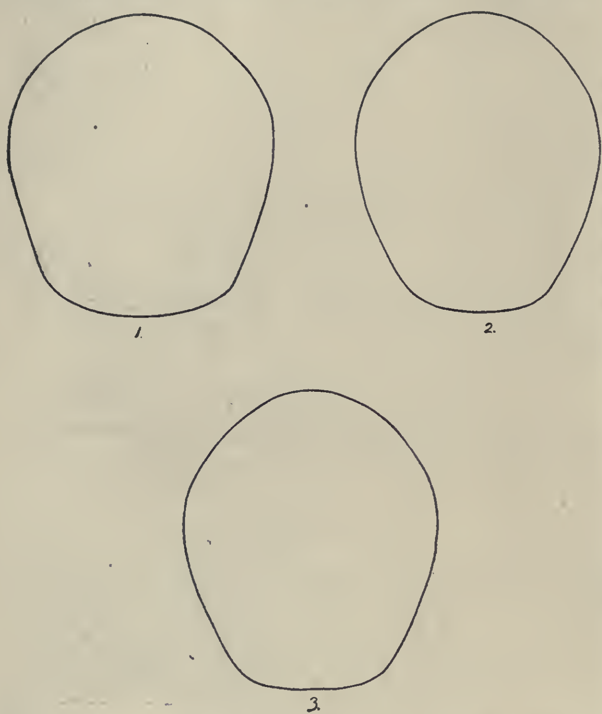

FIG. 2.—Sketches of head forms. Showing (1) the average form of the head of the foreign-born Hebrew; (2) the average form of the head of the foreign-born Sicilian; (3) the average form of the head of the American-born Hebrew and Sicilian born more than ten years after the arrival of the mother in America. These sketches are intended only to give an impression of the change in proportion. They do not represent the head forms in detail.

does not seem to be due entirely to inherited physiological causes nor to differences of nutrition. The fact, however, comes out with greatest clearness that reduction in the size of families goes hand in hand with the improvement of physical development.

The data upon which these conclusions are based are given in tables of measurements, and synthesised in curves. Their trustworthiness depends upon several conditions being carefully investigated. The wide experience of Prof. Boas as a physical anthropologist and his mastery of statistical methods give us confidence that his conclusions are well founded. He acknowledges that the problem is an exceedingly complicated one, and he describes the various ways in which he has endeavoured to arrive at trustworthy results; for these the reader is referred to the report.

One of the most important problems of physical anthropology is to determine what effect environment has upon the human species. In his address to the Anthropological Section of the British Association at the Dublin meeting in 1908, and again in his presidential address to the Royal Anthropological Institute on "The Influence of Environment on Man," delivered on January 25, 1910 (which will shortly be published), Prof. W. Ridgeway has directed attention to this question. Reference may also be made to Dr. R. Humphrey Marten's presidential address to the South Australian Branch of the British Medical Association (Adelaide, 1900), on "The Effects of Migration from the Northern to the Southern Hemisphere." The investigations Prof. Boas is now undertaking are of prime importance, as they are based on careful measurements, but many more similar studies must be made before general conclusions can be drawn. It is also obvious that this is not a matter of purely anthropological interest, but is of significance to the sociologist, and should not be neglected by the statesman.

A. C. HADDON.

PRESENT CONDITION OF AMERICAN BISON AND SEAL HERDS.

FROM the third annual report of the American Bison Society, recently published at Boston, we learn that the condition and prospects of the three herds of bison maintained by the Government of the United States are all that can be desired, and that, in the opinion of Dr. Hornaday, the future of the species is now secured. These herds comprise one in the Yellowstone Park, with ninety-five head, a second in Wichita, with nineteen head, and a third in Montana, with forty-seven head, the total number of animals thus being 161. Of these herds the one in Montana, which occupies a tract of twenty-nine square miles, has only recently been brought together (as described in the present report), and promises to be the best of the three. Indeed, Dr. Hornaday is of opinion that this herd alone would be sufficient to safeguard the species against extinction, since, owing to the extent of the area on which it is established, it is secure against any ill-effects from in-breeding. Regarding the Yellowstone herd, Dr. Hornaday is less confident, as the relatively small tract on which it is kept may lead to deterioration. The Wichita herd, on the other hand, is as well situated as the one in Montana.

In another part of the report is given a census of the total number of pure-bred bison living in captivity in America on May 1st, 1910. This total is 1633, against 1592 in 1908, and 1010 in 1903, thus showing a well-marked and progressive increase. Out of the 1633, 626 are in Canada, and the remaining 1007 in the United States. In 1903 Canada possessed only forty-one head, the enormous increase being apparently due to the transference of the Pablo herd from the United States. Of wild bison the total number is estimated at 475, of which twenty-five are in the Yellowstone, and the remaining 450 in Canada. In 1908 the number of wild Canadian bison was estimated at 300. The grand total of pure-bred animals living in North America is thus approximately 2108, against 1917 in 1908.

A considerable portion of the Montana herd was purchased from Mrs. Conrad, of Kalispell, in that State, who also presented the magnificent herd-bull shown in the foreground of the illustration herewith reproduced.

The selected portion of the Conrad herd was driven by cowboys, without any noise, to the nearest railway siding. Here "each animal was driven singly into the corral that communicated with the loading chute.

. . . The chute of a railway cattle-yard is a long, narrow cañon with wooden walls, sloping upward rather steeply, and ending in the open door of a cattle-car. . . . A crate was placed in the middle of the chute; the sliding door at the outward end of the box was lifted high and carefully poised for a quick drop. An animal specially fitting the crate was then cut out from the bunch, driven into the chute, driven on into the crate, and shut in with a bang. After that the crate was hauled and shoved into the stock-car and settled in its place."

In NATURE of July 28 appeared a paragraph relating to the danger threatening the Alaskan fur-seals owing to unrestricted pelagic sealing by the Japanese. Since that paragraph was written the editor has received a copy of an "open letter" addressed by the Camp-Fire Club of America to the people of the United States, together with certain letters addressed by the committee of the club to Mr. Secretary Nagel, and the replies to the same. From a covering letter it appears that the Camp-Fire Club comprises about 350 members, all interested in the preservation of American big game, and the opinions of whom ought therefore to carry considerable weight. According to the "open letter," the Pribilov Islands, when purchased from Russia about the year 1867, were the resort of at least 4,500,000 fur-seals, or sea-bears; at the present day the number is only from 30,000 to 50,000. Formerly the islands yielded a large revenue to Government; now they involve a heavy expenditure. The Camp-Fire Club is of opinion that all slaughter of seals on the islands should be prohibited for ten years, in order to permit of the recuperation of the herds to a point when they will yield an annual revenue of 200,000*l.*, and at the same time to make treaties with the British, Canadian, Japanese, and Mexican Governments for the suppression of pelagic sealing, the latter being an even more urgent matter than the former.

The secretary to Government, on the other hand, acting apparently on expert advice, demands a renewal of a killing licence on the ground that unless 95 per cent. of the younger male seals are annually killed the "surplus bulls" will fight with "the breeding bulls" over the females, and seriously retard the breeding of the herd. To this the committee, after indicating their opinion of the experts concerned by printing the word with inverted commas, make the following reply:—"As if a wild species does not know how to breed and multiply successfully without the help of man! The excuse is most inadequate, and in any event it is no excuse whatever for not dealing squarely with Congress, and in accordance with a very plain understanding."

From this it will be manifest that the controversy has entered a somewhat acute and embittered stage, the details of which I have neither space nor inclination to discuss. If, however, pelagic sealing weighs heavily, as I understand it does, on female seals, there may be something in the contention that a certain number of young males should be annually killed off, although 95 per cent. certainly seems a heavy toll. On the other hand, there is no doubt whatever that unrestricted pelagic sealing should be stopped, this being a matter, not of American, but likewise of world-wide interest. R. L.

The Best Bull Bison in the Montana Herd. (From the Third Annual Report of the American Bison Society.)

THE FUTURE OF AGRICULTURAL RESEARCH IN GREAT BRITAIN.[1]

THE announcement recently made to the effect that the Board of Agriculture has applied for a large sum of money from the development grant for the purpose of aiding agricultural research lends a peculiar interest to two publications just issued, the report of the Board of Agriculture on the grants made for the last two years for agriculture education and research, and the statement of the British Science Guild recently submitted to the Prime Minister in an influentially signed memorial. The report may

[1] Report on the Distribution of Grants for Agricultural Education and Research in the Years 1903–9 and 1909–10. Board of Agriculture and Fisheries. Cd. 5388. Price 7½*d.*
The British Science Guild. The Present Position of Agricultural Research in the United Kingdom.

be taken as an indication of the official attitude, and the memorial as the attitude of the professed man of science, towards agricultural research, and it is interesting to compare them, to see what they have in common and how far their differences are fundamental.

From the fact that both publications, after a few preliminary statements, come straight to one and the same point, we may take it that this is regarded as the real issue: Does Research pay? The position of the Board of Agriculture is thus set out:—

A public department when authorising the expenditure of money on research is bound to take into consideration the probable value of the work to the State. It cannot rest satisfied with the assurance that sooner or later all accessions to knowledge will benefit the country. The taxpayer of to-day naturally wishes to see a return for his contribution, if not in his own lifetime at least in that of his children. It is obvious therefore that, as a matter of elementary justice, the question of time must receive consideration from any department entrusted with the expenditure of State funds on research.

On the other hand, the memorial states:—

The committee of the British Science Guild would urge very strongly that the value of investigation can rarely be translated directly into terms of pecuniary gain. The benefits lie more in the method of thought that is induced among the farmers and those concerned in advising them, in the stimulus it gives to a more exact conduct of the business of farming, in the confidence with which men take up the fresh resources which science and the industries are always putting at the disposal of agriculture, than in any sudden revolutions effected by research. The fact that the countries whose agriculture has made the greatest advances in recent years are those which pay the greatest attention to research is itself sufficient justification for the action of the British Science Guild in urging the British Government to move in this direction.

Between these two positions there is a great gulf, but one may hope that it will not prove impassable. The Board of Agriculture has recently appointed a committee, including several distinguished men of science, to advise on questions dealing with research, and doubtless a broad view will be taken of "the probable value" of a piece of really good research work. The memorial gives several instances where research has directly resulted in financial gain to farmers. An outstanding case is the use of superphosphate, which was discovered by Sir John Lawes, and has been of enormous benefit to farmers. Denmark affords at least two good illustrations. Sonne's work on barley has resulted in the general adoption of a particular type of malting barley, so that the yield has gone up three or four bushels per acre, and the malting quality has become more uniform. The whole butter industry is founded on scientific control. Nilson's work in Gothland, Sweden, is also mentioned. More than 30,000 hectares of this island consisted of sterile swamps. Nilson proved by careful investigations that the factor causing sterility was deficiency of phosphates; when these were supplied the richest crops of corn, rape, and sugar-beet could be secured. He further devised a suitable phosphatic manure out of a rather poor phosphatic mineral in the north of Sweden. Coming to our own Colonies, the control of live stock diseases in the Transvaal furnishes an illustration.

At the end of the war the whole country was ravaged by various diseases, which had reached the country at an earlier period, but had been distributed broadcast by the movements of horses and stock during the war—rinderpest, redwater, East Coast fever, in succession had attacked the cattle, until few were left in the colony, and importations died as rapidly as they were introduced. Sheep and horses were equally affected, until stock raising of any description seemed an impossibility. The investigations, however, conducted by Dr. Theiler for the Transvaal Department of Agriculture into the causes of these diseases have resulted in a number of methods of immunisation, which, coupled with veterinary regulations as to the movements of stock, are now rendering the country habitable by cattle again and the business of agriculture once more possible.

Many other instances might have been given, but the memorialists very wisely do not allow themselves to be drawn into a false position, and repeatedly urge that the results of research work cannot usually be translated direct into terms of general practice. They decline, in short, to regard the probable financial value of a particular piece of work as the only criterion of its usefulness. This is, of course, the position one expects from the British Science Guild, but it must also be remembered that the attitude of the Board is unquestionably that of a large body of the public.

In reading the two publications it becomes evident that the word "research" is used in rather a different sense in each of them. The Board's report states that "research must satisfy one or both of two conditions (1) it must, as a result of observation or experiment, result in the collection of fresh facts; (2) it must involve an examination of the facts collected, or phenomena observed, and the reduction of them to a form in which they constitute an addition to knowledge." This definition is not adhered to, and work that is primarily educational, such as demonstration trials and tests, is apparently classed as research. The memorial recognises the difficulty of drawing a hard and fast line, but adopts this as a working definition:—"Work which is published only in the annual reports of the institution may be regarded as educational, work also published by one of the learned societies or in the *Journal of Agricultural Science* may be treated as research."

This difference of view explains why the memorialists only put the number of colleges where research has been done at seven, whilst the Board consider that research is being done at all the colleges. So far as the demonstration trials are concerned the Board's position is sound; such demonstrations are intended to improve practice, and must obviously be judged on their profitableness. Only in regard to research proper is there any difference of opinion, and here the difference is fundamental. It would, however, be premature and ungracious to labour this point; the Board's advisory committee is only just appointed, and it is clear that an open mind prevails:—"It is not usually a difficult task to distinguish research from spurious imitations, on the other hand it may at times be difficult to say whether a particular piece of research is, or is not, entitled to receive aid from agricultural funds. One may be permitted to express the hope that the public interested will not take a narrow view on this point."

The object of the British Science Guild memorial was to urge the necessity of "granting adequate assistance for the continuous conduct of scientific investigations having for their object the development of agricultural production." No scheme is foreshadowed; indeed, any attempt would have been out of place.

The report of the Board of Agriculture, whilst it does not set out a scheme, discusses the general lines on which one might be based. In the first instance, "At the present time the number of well-qualified men engaged in agricultural investigation in this country is relatively small and one of our chief aims in expending additional funds should be to establish a system which will bring agricultural science suitable recruits." But when we come to inquire the meaning of "suitable recruits," we learn that "the

chief demand of the present time is for 'spade workers' and 'quarrymen' to prepare foundations and material." It is to be hoped that on this point at least the Board will allow itself to be converted. Unless men of outstanding ability can be attracted to the research stations and agricultural colleges, there is not much hope that the taxpayer will see anything like the return he ought for the money expended. This, indeed, is the vital question; if the right sort of men are got to do the work all the other questions of administration sink into insignificance. But here also the Board is on what appears to be the safe ground. The idea of a central experimental station is dismissed, and a wider policy is suggested:—"It would probably be advisable, therefore, to use part of the Development Fund in making such grants to universities and university colleges as would induce them to make provision for agricultural research."

At no period in its history has agricultural science had a greater opportunity than at present. It is no longer hampered by lack of funds or by apathy on the part of the farmer. The problems are more numerous and more interesting than ever they were. But unfortunately the workers are few, and fresh workers are not readily forthcoming. The hopeful feature is that a number of eminent men of science are giving up time and thought to the organisation of the new work, and, further, that the Board of Agriculture and the large agricultural societies are manifestly and genuinely anxious to render all the help they can.

RATS AND PLAGUE.

ALTHOUGH the recent epidemics of bubonic plague in China, India, and other parts of the world have been always associated with outbreaks of the same disease amongst rats, the historical study of plague throughout the world reveals the singular fact that previous to 1800 very few references to a coincident mortality amongst rats have been put on record. Many excellent accounts of the older outbreaks, notably of the Black Death in Europe in 1347, and the Great Plague of London in 1665, are in existence, but careful research into these documents by modern historiographers—Haeser, Hirsch, Abel, and Sticker—has shown that for reasons difficult to discover very scanty mention of associated rat mortality has been made.

The earliest recorded instance is perhaps that given in the Bible in the account of the pestilence amongst the Philistines, which they ascribed apparently to "the mice that marred the land." Avicenna refers to the association between rats and plague in his description of the epidemic in Mesopotamia about the year 1000 A.D. Nicephorus Gregoras, writing of the Great Plague of 1348, which entered Europe by way of Constantinople, makes a similar reference. Rats are mentioned in connection with the plague in Yunnan about 1757, and later in 1871–3. In India an association between rats and plague is noted in the *Bhagavata Purana*, by the Emperor Jehangir in the plague epidemic of 1615, and in a report of the Pali plague in Rajputana in 1836. Lastly, Orraeus refers definitely to rat mortality in his account of the epidemic of 1771 in Moscow.

The identity of the disease in rats with that affecting man was established by the discovery in 1894 of *B. pestis* by Yersin and Kitasato.

Within the next few years the relationship between rat and human plague was investigated in many parts of the world—by Thompson and Tidswell in Sydney, Clark and Hunter in Hongkong, Snow, Weir, Hankin and James in India, and by Kitasato in Japan. In 1905 the Plague Research Commission was appointed to investigate plague in India, and the reports of this Commission represent the results of the most exhaustive inquiry into the subject that has yet been carried out.

The Commission early turned its attention to the relationship of rat plague and human plague, and instituted an extensive examination of the rats in Bombay and elsewhere for the presence of plague infection. The maps and charts, representing graphically the results of this examination, clearly show the correlation between the epizootic and the epidemic—the rat epizootic preceding the epidemic by an interval of ten to fourteen days. Every outbreak of bubonic[1] plague, when adequately investigated, was found to be associated with the disease amongst rats. The conclusion must be drawn that every epidemic of bubonic plague is caused by the concomitant rat plague.

In Bombay the rat population is an enormous one, *Mus decumanus* (the brown or grey rat) swarming in the sewers, gullies, and outhouses in the city, and *Mus rattus* (the black rat) living in countless numbers in the houses of the people. The latter species is of especial importance in plague epidemics, because it is essentially a house rat: it may almost be said to be a domesticated animal. The severity of the epizootics in the two species will be appreciated when it is stated that during one year the examination of 70,789 *M. decumanus*, taken from all parts of Bombay city, proved that 13,277 were plague-infected = 18·8 per cent., and that out of 46,302 *M. rattus* examined 4,381 were plague-infected = 9·4 per cent. The heavier incidence of plague in *M. decumanus* is explicable by the circumstance that the flea infestation of this species is more than twice that of *M. rattus*.

Some interesting observations on the distribution of different species of rats in India have been made recently by Captain R. E. Lloyd, I.M.S. The most common rats in India are *M. rattus*, *M. decumanus*, and *Gunomys* (*Nesokia bengalensis*). *M. decumanus* is common both in Bombay and Calcutta, but is absent from the city of Madras. It is significant that Madras is the one port in India which has never been seriously infected with plague. *M. rattus* appears to be universally distributed in India, whereas *M. decumanus* does not seem to occur in India except in seaports. *Nesokia bengalensis* is found in every part of India.

The question of the transportation of plague by ship rats is an extremely important one, but has not so far been thoroughly worked out. It would appear that *M. decumanus* is the species most commonly infesting ships, although *M. rattus* is also found.

Sticker, in his history of plague epidemics, quotes the statement that *M. decumanus* got into Europe from Persia about the year 1725. In England *M. rattus* was displaced by the invasion of *M. decumanus* about this time. At the present day the predominating species in this country is undoubtedly *M. decumanus*; *M. rattus* is, however, becoming increasingly common in the seaports.

An important question in plague epidemiology is the mode of conveyance of the infective organism from the plague rat to man. It is impossible even to summarise here the numerous experiments and observations on this subject, but it may be said that from many sides, and especially from experiments in the laboratory and in actual plague-infected houses, a mass of evidence has been raised which incriminates and indeed convicts the rat flea as the transmitting agent of the infection.

[1] Pneumonic plague differs from bubonic plague in its mode of spread. When a series of cases of plague pneumonia occurs, the infective organisms are conveyed directly from case to case by coughing and inhalation. It is probable that the usual source of infection in the first case of the series is a severe secondary pneumonia occurring in a patient with septicæmic plague.

In India the rat flea, *Loemopsylla cheopis*, which closely resembles the human flea, *Pulex irritans*, in appearance, is by far the most commonly found species. In England the common rat flea is *Ceratophyllus fasciatus*; a single specimen only of *L. cheopis* has been found up to the present time.

L. cheopis, especially if hungry, will bite man; *C. fasciatus* does not take to man with any readiness, but will undoubtedly bite on occasion. This difference in the appetite of the two species for human blood may be of significance in determining the likelihood of the spread of rat plague to human beings.

G. F. PETRIE.

PROF. D. P. PENHALLOW.

WE regret to announce that Prof. D. P. Penhallow, D.Sc., F.R.S. (Canada), president of the American Society of Naturalists, and professor of botany in McGill University, Canada, died on October 20, in consequence of an apoplectic seizure, whilst on board the ss. *Lake Manitoba*, on voyage to Liverpool. His remains were brought to Liverpool, and were, in accordance with his wishes, cremated at Anfield Cemetery on Friday, October 28. Prof. and Mrs. Penhallow were about to begin a year's vacation, and had intended spending the winter in the south of England. In consequence of the severe strain of work which Prof. Penhallow had undergone during the last few years, his previously excellent health had shown signs of giving way, and under medical advice he was about to take a prolonged rest, when the lamentable event of his decease occurred..

Prof. D. P. Penhallow was born in 1854 at Kittery Point, in Maine, where his parents had a summer cottage, but their home was in New Hampshire, and Prof. Penhallow always regarded himself as a New Hampshire man. His family were in the direct line of descent from Governor Wentworth, of pre-Revolutionary days, and Prof. Penhallow was a splendid embodiment of the best type of New Englander. He received his scientific education in Boston University, and after graduation he was offered the post of professor of botany in the Imperial College of Agriculture in Japan. In the same year (1876) he married Miss Sarah Dunlap, who, like himself, could boast of a distinguished New England ancestry, and the first four years of his married life were spent in Japan. He thus enjoyed the distinction of being one of the group of Western students who were chosen by the Reformed Japanese Government to inaugurate the epoch of Meiji (intellectual enlightenment) in Japan.

Returning to America in 1880, he undertook work in connection with the summer school of botany in Harvard University, and in 1883 he was offered the newly-created chair of botany in McGill University, Montreal, where the rest of his professional life was spent. He had a very uphill fight in Montreal, which he manfully fought. There was no botanical laboratory and there were no funds to provide one; but as Prof. Penhallow gained the respect and esteem of the community help was forthcoming, and before he died the botanical laboratory was exceedingly well equipped. When he was appointed obscurantist views prevailed in Montreal, both in the city and in the University, and Prof. Penhallow was one of the very first to teach evolution, and may thus be said to have helped to inaugurate the epoch of "meiji" in Montreal. In his own science he devoted special attention to the anatomy of woods, both recent and fossil; on this subject he published many valuable papers, and in his great work on "Gymnosperms," which appeared in 1908, he summed up the results of twenty years' labour. His eminence in his special department was cordially recognised by the American scientific world, and when he died he was not only president of the American Society of Naturalists, but vice-president of the American Society of Botanists.

But Prof. Penhallow's activities were by no means limited to teaching in his special subject. He threw himself into every movement calculated to bring a wider intellectual outlook into Montreal and Canada generally. He instituted courses of lectures to teachers, which had for many years a beneficial effect on those engaged in instruction in the public schools of the city. He was a leading member of the Canadian Royal Society, and in 1897, when the British Association met in Toronto, he was appointed a member of a committee to impress on the Canadian Government the desirability of founding a marine biological station. The Government acted in accordance with the advice of this committee, and in 1899 a small floating station was started, which was moved from placed to place in eastern Canadian waters.

When in 1907 the Government was persuaded to give a grant towards the foundation of a permanent station at St. Andrews, Prof. Penhallow was deputed by the Biological Board to supervise its erection. When he arrived at St. Andrews it was found to be necessary not only to build the station, but to cut a road through a mile of forest and to build a wharf. No one was ready to undertake the contract for this work, and those who were ready to undertake part of it, when they discovered that it was to be paid for by "Government money," would only do so at exorbitant prices. With characteristic American energy and versatility, Prof. Penhallow threw himself into the breach, became contractor himself, and constructed the road, the station, and the wharf in one-third the time he was told it would require, and at a great saving in cost. Next year he superintended the activities of the station, but a political crisis at Ottawa temporarily stopped supplies, and the anxiety and financial strain which he underwent undermined his health, and, in the opinion of his friends, constituted the first link in the chain of causes which led to his death.

Prof. Penhallow is survived by his wife and by his son, Dr. P. Penhallow, who is engaged in medical practice in Boston. By his death McGill University loses one of its most distinguished professors, the city of Montreal one of its most public-spirited citizens, and the science, not only of botany, but of marine biology generally, a devoted supporter who could ill be spared.

E. W. M.

NOTES.

WE learn with great regret that it has been found necessary to postpone the festivities arranged to take place at Leyden to-day (November 3). On this date Prof. van Bemmelen completes his eightieth year, and he was to have received the personal congratulations of friends and disciples from all parts of the world. Owing to his illness, the ceremony is to be confined to the formal presentation of the jubilee volume by Prof. Lorentz, if, as is hoped, Prof. van Bemmelen is sufficiently recovered to receive him. The jubilee volume is a remarkable testimony to the regard which is felt throughout the world for the distinguished second founder of colloidal chemistry. It contains a portrait, together with a biography and a bibliography of the professor's published works. Sixty papers on subjects connected with the colloidal state have been contributed by workers from all parts of the world. Amongst the authors are le Chatelier, Duhem, Zsigmondy, Liesegang, von Wiemarn, Hissink, Freundlich, Biltz, Spring, Hardy, Svedborg, Jordis, Wolf. Ostwald, Lotter-

moser, Nietzk, Spiro, Bechold, Tamman, Barus, Bredig, Lorenz, Malfitano, &c. The volume is published by C. de Boer, Helder, Holland.

THE Allahabad *Pioneer Mail* of October 7 contains a melancholy review of a resolution recently passed by the Punjab Government regarding the prevention of plague. This resolution records that, in the opinion of a committee consisting of plague experts and district officers of experience, "no remedy has been found for the disease; that the people generally will not go to plague doctors to be treated when suffering from plague; that disinfection of houses by means of chemicals, or even by heat, as a means for checking or preventing an epidemic is useless; that rat destruction by poison or trapping is almost equally useless; and that inoculation, though a splendid means of individual protection, cannot be used to check the epidemic owing to popular prejudice." As the result of this, the Punjab Government propose, while keeping on the field the establishment of plague doctors, to reduce the cost if possible, and make suggestions as to how this can be done. It is not easy from this report in the *Pioneer Mail* to analyse the evidence upon which the Punjab Government acts, but the paper must cause melancholy reflections among the friends of India. Is it not true that the words *non possumus* are somewhat frequently heard from the mouth of the Government of India? We have just listened to them in connection with malaria prevention, and we have heard them over and over again in connection with the prevention of cholera. Perhaps a complete reform in the sanitary service of the country, with much more attention to sanitary investigation and a more generous employment of trained scientific workers, would not only save the Government the waste of much money on fruitless efforts, but would also do more to ensure success in the future.

COLONEL W. C. GORGAS, who has done such splendid work in removing mosquito-borne diseases from the Panama Canal zone, sends a short letter to the *Times* of October 28 in which he gives the death-rates for that area; and they are so remarkable that we here reprint his facts. Colonel Gorgas says:—"For the years since our occupation the statistics for the city of Panama have been as follows:—

Year	Population	No. of deaths	Death-rate per 1000
1905	21,984	1,447	65·82
1906	25,518	1,142	44·75
1907	33,548	1,156	34·45
1908	37,073	1,292	34·83
1909	40,801	1,038	25·44

The rates for the Canal Zone, under American jurisdiction, including the cities of Colon and Panama, are as follows:—

Year	Population	No. of deaths	Death-rate per 1000
1905	56,624	2,828	49·94
1906	73,264	3,544	48·37
1907	102,133	3,435	33·63
1908	120,097	2,983	24·83
1909	135,180	2,459	18·19

Among employés the rates have been as follows:—

Year	Employés	Death-rate per 1000
1905	16,511	25·86
1906	26,475	41·73
1907	39,343	28·74
1908	43,890	13·01
1909	47,167	10·64

There has been no case of either plague or yellow fever on the Isthmus since 1905. We admitted to our hospitals for malaria in the year 1905, 514 cases for each thousand employés; in 1906, 821 cases for each thousand employés; in 1907, 424 for each thousand employés; 1908, 282 for each thousand employés; and 1909, 215 for each thousand employés."

THERE seems little doubt that the four deaths reported recently at Freston, in Suffolk, were due to plague. To prevent any further development of the disease, active measures are being adopted to effect a general destruction of rats in Freston and the neighbourhood. The southern part of rural Ipswich has been systematically explored, and large quantities of poison laid down. The Samford Rural District Council has issued a warning notice pointing out that it is dangerous to touch dead rats with the naked hand, and urging their burial without delay. The public has been requested not to eat rabbits or hares killed in the district. The notice also urges a general campaign against uncleanliness and insects. The question of destroying rats over a wider area than that proposed has been raised, as many dead rodents have been found north of the Orwell. It is pointed out that the increase of rats can be traced to the practical extinction of their natural enemies—owls, kestrels, and hawks, which are now seldom seen in the locality. The origin of the disease is still uncertain, but there is reason to believe, in view of the plague at Odessa, that grain vessels from the Black Sea to the River Orwell may have brought over plague-stricken rats. The position of knowledge as regards the relation between rats and the spread of plague is described in an article elsewhere in this issue.

IN the gardens of the Zoological Society of London, Regent's Park, there is now in flower a specimen of *Agave Americana*. The Agaves are popularly known as "American" Aloes; but there are no true Aloes in America, the genus being almost entirely confined to South Africa. Agave is a member of the natural order Amaryllidaceæ, and Aloë of the natural order Liliaceæ. Another popular fallacy connected with the Agaves is the belief that the plants flower after 100 years and then die, hence the Agave is sometimes called the century plant. The facts are these, that the plants, being monocarpic, are only capable of flowering once, but the age at which a particular specimen will flower is determined by many circumstances, including constitutional characters and the suitability or otherwise of the conditions in which the plant is growing. These remarks apply specially to *Agave Americana*, for another species, namely, *A. Sartori*, is capable of flowering from year to year. *A. Americana* has very thick leaves of from 4 feet to 6 feet in length. They have sharp prickles all along the margins, and each leaf has a stiff, sharp point 1 inch to 2 inches long; these latter are sometimes called "Adam's needles." The plant contains fibre in the roots and leaves, and the fibre is used for commercial purposes. Agaves are cultivated for ornamental purposes in this country, being used frequently as terrace plants in large boxes or tubs. The flower spikes grow very rapidly when once they have formed, their height varying from about 15 feet to upwards of 20 feet. The numerous flowers are greenish-yellow, occasionally quite yellow, but scarcely golden as they are sometimes described. The plant which is now flowering at Regent's Park has stood out of doors during the summer, but it is blooming in the warm atmosphere of the reptile house. Another specimen bloomed in the same gardens in 1906, and two specimens flowered in the Victoria Park, London, in 1902. In Mr. Smith's gardens in the Scilly Islands a dozen or more specimens flowered out of doors in 1875, and in the south of France Agaves in flower are not un-

common objects. There is a variegated variety of *A. Americana* which is more ornamental than the type.

It is announced in the *Revue scientifique* that Prof. Kammerling Onnes, of the University of Leyden, has put his cryogenic laboratory at the disposal of Madame Curie for her researches on radio-activity at low temperatures.

The daily Press has recently given currency to a vague report that a "vast lake" has been discovered in an unexplored part of north-western Canada by Indians, which they declare to be as large as Lake Superior. The report is hardly likely to be correct so far as the size of the lake is concerned.

A course of twelve lectures on "The Coasts of Great Britain and Ireland" (Swiney lectures on geology) will be delivered by Dr. T. J. Jehu in the lecture theatre of the Victoria and Albert Museum, South Kensington, on Mondays and Tuesdays at 5 p.m., and Saturdays at 3 p.m., beginning Saturday, November 5. Admission to the course is free.

A Reuter message from Vienna states that on October 28 the Radium Institute created there by the Academy of Sciences was formally opened by the Archduke Rainer. The new institute is to be devoted solely to chemical and physical research, and will be open to scientific men of all countries. The institute has at its disposal three grams of radium from Joachimsthal.

At the annual general meeting of the Cambridge Philosophical Society, held on October 31, the following officers were elected:—*President*, Sir George H. Darwin, K.C.B.; *vice-presidents*, Dr. Fenton, Prof. A. C. Seward, and Prof. H. F. Newall; *treasurer*, Prof. E. W. Hobson; *secretaries*, Mr. A. E. Shipley, Dr. Barnes, and Mr. A. Wood. The new members of the council elected are Mr. E. A. Newell Arber, Sir Joseph J. Thomson, and Mr. J. E. Purvis.

The Chemical Society's banquet to past presidents, which was postponed from May 26, will be held at the Savoy Hotel (Embankment entrance) on Friday, November 11. The banquet is in honour of the following past presidents who have attained their jubilee as fellows of the society:—Prof. William Odling, F.R.S., the Rt. Hon. Sir Henry E. Roscoe, F.R.S., Sir William Crookes, F.R.S., Dr. Hugo Müller, F.R.S., and Dr. A. G. Vernon Harcourt, F.R.S.

The Berlin correspondent of the *Times* states that the German Ministry of the Interior has called a meeting to be held within the next few days to consider whether the foundation of a special institute for aviation research is practicable, or whether the work can be better carried out by existing institutions. Delegates from the Imperial Government and the Federal States will be present, together with representatives of the German technical universities, of various associations connected with aviation and motors, and of the industries concerned.

The death is announced of Dr. D. J. B. Gernez, member of the Paris Academy of Sciences and a former collaborator of Pasteur. From a notice in the *Times* we learn that Dr. Gernez was born in 1834. On the completion of his studies he filled various posts as a teacher of scientific subjects. While engaged upon professorial work at the Lycée Louis-le-Grand he assisted Pasteur in some of his researches, and was for many years an intimate friend and collaborator of the great French investigator. For more than twenty years Dr. Gernez was a lecturer at the Ecole Normale of Paris, a post which he held simultaneously with professorships at other great educational institutions, and from which he retired in 1904. Dr. Gernez was the author of a number of treatises on scientific subjects, and was an Officer of the Légion d'Honneur.

At the general meeting of the Royal Society of Edinburgh, held on October 24, the following office-bearers were elected:—*President*, Sir William Turner, K.C.B., F.R.S.; *vice-presidents*, Prof. Crum Brown, F.R.S., Prof. J. C. Ewart, F.R.S., Dr. J. Horne, F.R.S., Dr. J. Burgess, Prof. T. Hudson Beare, Prof. F. O. Bower, F.R.S.; *general secretary*, Prof. G. Chrystal; *secretaries to ordinary meetings*, Dr. C. G. Knott, Dr. R. Kidston, F.R.S.; *treasurer*, Mr. J. Currie; *curator of library and museum*, Dr. J. S. Black; *councillors*, Prof. J. W. Gregory, F.R.S.; Dr. A. P. Laurie, Prof. Wm. Peddie, Prof. H. M. Macdonald, F.R.S., Prof. D. Noël Paton, Dr. W. S. Bruce, Prof. F. G. Baily, Dr. J. G. Bartholomew, Dr. R. H. Traquair, F.R.S., Prof. James Walker, F.R.S., Prof. A. Robinson, and Dr. W. S. M'Cormick.

A meeting of the Optical Convention executive committee was held on October 25 in the rooms of the Chemical Society to consider the desirability of holding a second convention in the year 1912. On the motion of Dr. R. T. Glazebrook, C.B., F.R.S., it was resolved that a meeting of the permanent committee, which all members of the trade and others interested be invited to attend, be held some time in November to consider what action should be taken with the view of organising an optical convention in 1912. The time and place for this meeting will be announced as early as possible. The chair will be taken by Dr. Glazebrook, director of the National Physical Laboratory, as chairman of the permanent committee, and a statement of the principal matters to be brought forward for consideration at the meeting will be published in due course.

The magnetic survey yacht *Carnegie* left Para, at the mouth of the Amazon, under the command of Mr. W. J. Peters, on October 15, bound for Rio de Janeiro. This vessel, since leaving Brooklyn last June on her present cruise of three years in the Atlantic, Indian and Pacific Oceans, had covered nearly 7000 miles up to Para, during which portions of the first cruise were several times intersected by the introduction of loops. It is reported that the magnetic results obtained on the present cruise up to Para have fully confirmed the errors revealed by the first cruise in the existing magnetic charts of the North Atlantic. From Rio de Janeiro the *Carnegie* will proceed to Montevideo and Buenos Aires, and thence across to Cape Town, where she is due towards the end of March, 1911. At the latter port the director, Dr. Bauer, expects to rejoin the vessel, and be with her on the portion of the cruise in the Indian Ocean. *En route* to Cape Town, Dr. Bauer is to visit certain magnetic institutions in Europe in order to perfect arrangements for coöperative magnetic survey work.

The *Morning Post* National Fund Airship made a flight from Moisson to Aldershot on October 26. The airship left Moisson at 10 a.m. (French time), the coast of France near St. Valery en Caux at 12 noon, passed over the English coast-line near Rottingdean at 2.18 p.m., and reached Aldershot at 3.28 p.m., being brought to earth at 4.5 p.m. The distance of 197 miles was accomplished in 5h. 28m. The rate of speed was about 36 miles an hour, including partially adverse wind conditions. The airship carried a crew of eight. During the journey 528 lb. of ballast were used; 400 litres of petrol were consumed by

the engines, and at the moment of landing there were 880 lb. of water ballast, 990 lb. of petrol in reserve, in addition to at least 200 litres in the reservoirs. The engines started at 850 revolutions; they then worked up to 900 revolutions, and fell again to 850, and only finally during the landing worked at their full power of 1000 revolutions. The highest altitude reached was 2120 feet, and throughout the sea passage there was a steady level of about 200 feet. The overall length of the airship is 337·75 feet, and the water- and gas-proof envelope has a capacity of 353,165·8 cubic feet.

An appeal is made for funds to erect a new building for the Royal Society of Medicine. Of the sum required, the society has already provided 17,000*l*., and it asks that not less than 26,000*l*. may be contributed from without, so that it may not be compelled to curtail its very valuable public and scientific work. Towards the money in hand 8500*l*. has been subscribed by members of the medical profession. The Lord Mayor has become chairman of a Mansion House committee formed to promote the raising of upwards of 30,000*l*. for the new building. The governor of the Bank of England has opened an account for the receipt of donations, which may be sent to the Bank of England, payable to "The Royal Society of Medicine Building Fund," or to the Lord Mayor at the Mansion House. The society now has 3200 fellows and members, and possesses a library of nearly 100,000 volumes. It was originally founded in 1805, under the name of "The Royal Medical and Chirurgical Society." A new charter was granted it in 1905 under the new name of "The Royal Society of Medicine."

SEVERAL of the Parisian hospitals entertained their visitors last Christmas to kinematograph exhibitions, in which very realistic phases in the life-history of various pathogenic organisms were thrown on the lantern screen. On October 28 Messrs. Pathé Frères, of Paris, gave the members of the Medical Society of King's College Hospital an opportunity of seeing some of their most successful applications of the kinematograph to bacteriological photomicrography. The films shown represented (1) the experimental production of sleeping sickness in a rat, and the movements of the trypanosomes in the blood; (2) the spirochæta of recurrent fever, and the ticks which convey the parasite; (3) the spirochæta of fowls, some of which were seen imprisoned and revolving within the red corpuscles; (4) the movements of the infusoria from the intestine of a mouse; (5) *Trypanosoma lewisi* of the rat; (6) *Spirochaeta pallida*, which, although only 1/2000th of a millimetre in width, could be followed in its movements across the field of the microscope. Other films were shown representing involuntary movements of the embryo of the Axolotl and its emergence from the egg, and the movements of the human stomach as seen during an X-ray examination of a patient. There can be no doubt that these films are a triumph of technique, but the gain at present is rather in favour of the public entertainer than of the worker in science. The main advantage from a scientific point of view is that rapid movements may be slowed and analysed, while slow movements may be accelerated, and thus realised. Such films will become an essential part of the equipment of every physiological and medical workroom.

THREE years ago the council of the Royal College of Surgeons, England, instituted demonstrations in connection with the museum. At one of these, given in the theatre of the college on October 28, the conservator, Dr. Arthur Keith, showed a series of specimens illustrating irregularities in the differentiation of sexual characters. The museum is peculiarly rich in specimens of this nature owing to the fact that John Hunter, its founder, had preserved many preparations which illustrated the influence of the sexual organs in determining the growth and features of many parts of the body. Amongst these are the specimens which show the assumption of the male plumage of aged pea-hens and hen pheasants. Preparations added to the museum by Mr. S. G. Shattock show that such an alteration of secondary sexual characters is accompanied by a change in the sexual glands, usually of an atrophic nature. A Leghorn fowl, in which the external characters were those of a cock rather than of a hen, had genital glands of an ovo-testicular type. The Hunterian preparations, illustrating the sexual organs of the "Free-Martin"—a form of ox born as the twin of a perfect bull calf—were also exhibited. Although these specimens had been preserved for more than 150 years, their tissue was in perfect condition for microscopical examination. In one case Hunter was of opinion that both testes and ovaries were present in the same individual (a true hermaphrodite), but on microscopical examination it was found that the "ovary" was really a mass formed by a remnant of the Wolffian body. A higher vertebrate with both testes and ovary has not yet been seen. Hunter explained all irregularities in the development of the accessory sexual organs and of "secondary" sexual characters as the result of an "imperfection" in the development of the testis and ovary. All museum specimens and recent experiments are in favour of his interpretation.

THE third part of the fourth volume of Memoirs of the Peabody Museum is devoted to an account by Mr. Teobert Maler of a series of adventurous journeys starting from the north of Yucatan and extending to the great lake of Peten-itza, in Guatemala. The value of the memoir would have been enhanced by a sketch of the routes, which are not traceable on ordinary maps. Several important sites representative of the Maya-Toltec culture were identified, such as Motul, where a remarkable stela depicting a pair of dancing priests was found, Tubusil, Silbituk, and the remarkable island city of Itza-Flores. When the country passes under the control of a decent government the great lake of Peten will be brought into connection with the sea, and vast economical resources of this region will be developed, with the result that the remarkable ruined cities connected with the career of Cortes will receive adequate examination.

IN the *Oxford and Cambridge Review* for Michaelmas term Dr. A. Smythe Palmer concludes his study on the luck of the horse-shoe. He arrives at the conclusion that it is derived from the cult of the new moon, which was adopted by primitive races as a symbol of recovery and good fortune. Incidentally, he has collected some curious examples to show that the symbol was regarded as possessing magical power among the prehistoric people of Europe, as is proved by various records of the discovery of horse-shoes in ancient interments, by the shape of many tumuli, and by the ring of trilithons at Stonehenge. He further points out that, following Babylonian precedent, the rising moon lying on her back was believed to be a silver boat. He thus disposes of the controversy between two sets of people who use the talisman in our days—one preferring to fix it with the heels upwards, the other downwards—in favour of the former.

IN the *Field* of October 22 Mr. Lydekker points out that the new antelope described in NATURE of September 29 (p. 397) as *Strepsiceros buxtoni*, with the alternative name of *Tragelaphus buxtoni*, should be known by the latter title.

IN the *Zoologist* for October Mr. F. J. Stubbs adduces further evidence, especially an Act of 1564 (2 Eliz. c. 15), to show that egrets were formerly common in England. "At the middle of the sixteenth century England was the home of an egret that was highly esteemed for the table. It nested with us, and was protected by law; and the same, or an allied, species inhabited an adjacent part of the Continent, and was brought to this country alive for food. Probably the bird was not altogether white, thus differing from any existing European egrets or herons, and resembling species now found in America."

VARIATION in the oyster-boring whelk (*Urosalpinx cinereus*) forms the subject of an article by Dr. H. E. Walter in the October number of the *American Naturalist*. This mollusc is a native of the Atlantic coast of North America, but was unavoidably introduced when oysters were transplanted to the Pacific shore. It was the original object of the article to compare these introduced Californian whelks with their Atlantic prototypes, but comparisons were extended to a wider basis. As the result of the investigation, it appears doubtful whether Urosalpinx is more variable in its new than in its original home.

As fossilised birds' feathers have hitherto been recorded from only some fourteen localities—with one exception of Tertiary age—brief reference may be made to Mr. F. Chapman's description in vol. xxiii., part i., of the Proceedings of the Royal Society of Victoria, of a fossil of this nature from the Tertiary ironstone of Redruth, Victoria. No definite determination of the genus of the specimen, which is in the form of impressions on the two halves of a split nodule, is attempted, although it is suggested that it may have belonged to one of the smaller waders, such as the ibises.

THE third botanical number of the current volume of the *Philippine Journal of Science* contains a compilation of new or noteworthy Philippine plants, and a sixth part of an index to Philippine botanical literature, both prepared by Mr. E. D. Merrill. Among the new plants, about a hundred in number, mostly trees or shrubs, there are eleven additions to the genus Ardisia, ten to Ixora, and six to Hiptage; also new genera, Astrocalyx and Cephalomedinilla, are proposed under the family Melastomaceæ, Curraniodendron under Saxifragaceæ, and Pygmæopremna under Verbenaceæ. With reference to Ixora, it is noted that *Ixora coccinea* does not grow wild, but a closely allied species, *I. philippinensis*, is abundant and widely distributed.

AN enumeration of twenty-eight flowering plants and ferns growing on a London building site, about half an acre in extent, in Farringdon Street that has been vacant for two years is communicated by Mr. J. C. Shenstone to the *Selborne Magazine* (October). As the author points out, the chief interest lies in the methods of distribution by which the plants have reached the spot, and he has classed them as wind-distributed, kitchen refuse weeds, and forage or packing weeds. It is extremely puzzling to find a growth of bracken fern, since the plant is very difficult to transplant, and the appearance of *Ficus Carica* is not immediately explicable. Three casuals, that is, plants not indigenous to Britain, are provided by *Epilobium angustifolium*, *Senecio viscosus*, and *Erigeron canadense*.

OF the flowers which undergo marked changes after fertilisation, tropical orchids afford some striking examples. For instance, it frequently happens that after the pollinia reach the stigma the flowers fade prematurely, the column swells, the stigmatic surface becomes enclosed, and eventually the ovules begin to develop. It would generally be assumed that these changes can only be induced by the stimulus of the pollen on the stigmatic surface, and the subsequent growth of the pollen tube. It has, however, been observed by Dr. H. Fitting, as is pointed out in the *Gardener's Chronicle* (October 29), that certain of these effects can be produced by inorganic means. Thus scratching the stigmatic surface suffices to cause premature withering, and the application of dead pollinia or an extract therefrom may bring about swelling of the column; but apparently development of the ovules does require the stimulus induced by the pollen grains penetrating the ovary.

AMONG the numerous articles now appearing in agricultural publications on the growth of sugar-beet in England, one, by Mr. Chas. Bathurst, M.P., in the *Agricultural Students' Gazette* (vol. xv., part i.) deserves some attention. The importation of beet sugar into Great Britain is steadily increasing, and amounted in 1908 to nearly eighteen and a half million pounds sterling in value. Much of this could be produced in England, but the operation of the sugar bounties rendered the industry financially impracticable. Now that the bounties are abolished by the Sugar Convention, active steps are being taken in several counties to start factories, which, in Mr. Bathurst's view, should prove distinctly profitable unless an excise duty is placed on the sugar. An average crop is given as 18 tons per acre, selling at the factory for 18*s*. per ton, or 16*l*. 4*s*. The cost of production, including the rent of the land, should not exceed 9*l*. per acre, leaving a profit to the cultivator of 7*l*. 4*s*. per acre.

THE summary of the weather issued by the Meteorological Office shows that for the eight weeks of autumn as yet expired the aggregate rainfall has been largely deficient over the entire area of the British Islands. The greatest deficiency occurs in the north of Scotland, where the total rainfall is only 2·89 inches, which is 6·24 inches less than the average of the corresponding period for the last twenty-five years. In the west of Scotland the deficiency is 5·13 inches, the aggregate rainfall being only 3·10 inches. In the north of Ireland the deficiency is 3·98 inches, and in the north-west of England 3·60 inches. In the south-east of England, which comprises London, the deficiency amounts to 1·16 inches. The duration of bright sunshine for the period is deficient, except in a few northern districts, the greatest deficiency being fifty-eight hours in the east of England and fifty-six hours in the Midland counties. The mean temperature was not very different from the average, but its maximum readings were lower than usual, the absolutely highest temperature since September 4 being 76°, in the Midland counties. Frost at night has, as yet, only occurred in a very few districts. The aggregate rainfall since the commencement of the year is not very different from the average, but there is an excess, except in a few of the northern districts. The duration of bright sunshine as yet this year is generally deficient, the deficiency exceeding one hundred hours in the eastern districts of England.

IN the Proceedings of the Amsterdam Academy of Sciences of June 25 Dr. W. van Bemmelen and Dr. C. Braak give a preliminary report upon the investigation of the upper air, begun at Batavia in 1909. The observatory is now equipped with registering balloons and suitable instruments, but it was thought advisable to proceed cautiously in using them so near to the sea before obtaining more knowledge of the drift of the upper currents by means of pilot balloons. The following data showing the

mean decrease of the temperature gradient per 100 metres of the lower 2 kilometres were obtained (1) above the land with a captive balloon and light wind; (2) above the land with a moderate westerly wind, with kites; and (3) above the sea (January 14–20), weather rainy, with kites; but the results are not strictly comparable, owing to differences of time of day:—

Metres	100–500	500–1000	1000–1500
Balloon ...	0·77° C. ...	0·57° ...	—
Kite (land)...	0·87 ...	0·72 ...	0·44° (<1500 M)
Kite (sea) ...	0·91 ...	0·59 ...	0·71

Further kite observations over sea gave for 1500–2000 m., 0·34°; 2000–2500 m., 0·50°; 2500–3000 m., 0·46°. At about 1000 m. the gradient shows a sudden decrease, probably due to the formation of cumulus clouds. The observations of wind direction for the period September–May show that the upper air-current has easterly components up to the greatest heights attained (10–15 km.). The average altitude of the west monsoon was 5·4 km. The upper easterly, as well as the lower westerly, winds were sometimes affected by strong northerly or southerly components. It is mentioned that diagrams of a registering balloon sent up on May 19, during the passage of the earth through the tail of Halley's comet, showed no other noteworthy feature than an inversion of temperature between 6 and 7 km.; the balloon burst at about 7 km.

THE various methods of finding the height of an airship are discussed by Captain Paul Renard in the *Revue scientifique* for September 17. Of the several methods of observing the height from the airship itself, Captain Renard considers that the use of the barometer affords the only practicable one. Of the methods of observing the height from the ground the large majority involve simultaneous measurement of several angles, and this is, in general, impracticable. Captain Renard considers that the best methods are by observation with a telemeter, coupled with a determination of the altitude, or by two simultaneous observations of the altitude at the instant the airship is in the vertical plane joining the two observers.

THE *Builder* for October 29 contains an illustrated article descriptive of the fine building now being erected in London for the Y.M.C.A. This building occupies an island site of some 33,000 square feet, bounded by Great Russell Street, Bedford Avenue, Tottenham Court Road, and Caroline Street. Reinforced concrete plays an important part, and has been employed for the solution of various structural problems of considerable magnitude. The building is not one of the reinforced concrete skeleton class merely sheathed in masonry, but rather is a combination of masonry with reinforced concrete, the latter material taking the duties hitherto very generally assigned to structural steel-work in modern architecture. Thus we find reinforced concrete columns, beams, and wall lintels forming the backbone of masonry features, and bearing a large proportion of the loads to be supported, yet without involving any noticeable departure from the familiar aspect of masonry. In some important respects reinforced concrete is exclusively adopted, as in floor, roof, gallery stairway, and swimming-bath construction, and in the form of exceptionally large girders. The details of the reinforced concrete work were prepared by Messrs. L. G. Mouchel and Partners, in accordance with the Hennebique system.

AN article by Mr. Fullerton L. Waldo on recent progress in the construction of the Panama Canal appears in the *Engineering Magazine* for October. Rapid progress has been made in the great lock-works and the huge dam that is rising at Gatun. The three lock flights divide the vertical distance to the 85-foot level between them, whereas the locks of the Pacific division have lifts of $33\frac{1}{3}$ feet and $54\frac{2}{3}$ feet respectively. The usable dimensions of the locks are 1000 feet by 110 feet, giving ample margin for even the new White Star liners, the overall dimensions of which are 890 feet in length and 92 feet in width. It is calculated that the lock-stair at Gatun will require about $1\frac{1}{2}$ hours for the transit; the Pacific locks will detain the vessels for about the same length of time. The total passage across the Isthmus will take about 10 to 12 hours. The train takes about $2\frac{1}{2}$ hours, so that passengers will probably prefer this method of transit. About 15 minutes are required to fill the lock chamber, but in case of need for haste the process can be completed in about half this time. The available water supply will allow of 48 lockages per day, which might mean an average of something like 80,000,000 tons of traffic annually as compared with 21,000,000 tons in the case of the Suez Canal and the 40,000,000 tons of the Sault Ste. Marie.

WE have received the first five numbers of a leaflet entitled *Hygieia*, which is published by the Bureau of the International Congress of Hygiene, which is to be held in Dresden in 1911. It contains notices with regard to the congress and brief abstracts of papers dealing with subjects appertaining to hygiene, *e.g.* sugar as a food-stuff, taverns as hospitals, cleansing of towns, &c.

MESSRS. NEWTON AND CO., Fleet Street, London, have issued a supplementary list of lantern-slides for the present session. Among many others, we notice numerous astronomical slides dealing with Halley's comet, the moon, and Greenwich Observatory; a set of slides showing Sicily and Messina after the earthquake; sets to illustrate eight lectures on India, drawn up by Mr. H. J. Mackinder for the Visual Instruction Committee; and slides showing aërial experiments and aëroplanes.

THE Penny Science Lectures at the Royal Victoria Hall, Waterloo Road, S.E., during November include:—November 8, "Early Men in Britain," W. Lower Carter, and November 22, "Liquid Air," Dr. R. Whittan Gray.

MR. H. K. LEWIS, of Gower Street, London, has published a catalogue of new books and new editions added to his well-known medical and scientific circulating library during July, August, and September of this year.

OUR ASTRONOMICAL COLUMN.

FIREBALL OF OCTOBER 23.—Mr. W. F. Denning writes:—"The fireball of Sunday, October 23, 8h. 12m., was observed at Kenley (Surrey), Ilford (Essex), and in Wales, as well as at other places. It appears to have passed over the sea N.E. of the mouth of the Thames at heights of 84 to 40 miles. The length of the luminous course was about 75 miles, and the velocity 19 miles per second. Radiant near α Arietis.

"The observation of the meteor from stations in Wales is interesting, and it is probable that the object was seen from a great many towns in England, for it appeared at a time when many people would be out of doors. The sky was, it is true, cloudy at some places and veiled the brilliant light of the meteor, but it was a very fine one, and gave several flashes as it slowly sailed along the E.N.E. as seen from the neighbourhood of London. It is important that if any further observations of an exact character were made they should be published, so that the flight of the object may be investigated accurately."

THE MOTION OF MOLECULES IN THE TAIL OF HALLEY'S COMET.—In a recent note in these columns (September 29, p. 404) attention was directed to some results published

by Prof. Lowell in which he showed that particles repelled by light-pressure along the tail of Halley's comet travelled with accelerating velocities. An important addition to these results is now published in No. 48 of the Lowell Observatory Bulletins. By comparing the images shown on direct photographs with those shown on contemporaneous objective-prism spectrograms, taken under conditions which permit the comparison, Prof. Lowell has educed evidence that the gaseous molecules of the tail were repelled by light-pressure.

A series of spectrograms, taken during April and May, shows that the constituents of the tail varied considerably from one date to another. But the evidence indicates that on May 23 about 70 per cent. of the radiations represented on the spectrograms was due to emission, the remaining 30 per cent. being taken up by the continuous spectrum. That is to say, that the knots previously measured, on the direct photographs for May 23, were composed chiefly of gaseous molecules. As these knots showed, by their accelerating velocities, the action of a repulsive force exerted from the sun, it follows that light-pressure is competent to repel gaseous molecules.

Confirmation of this important result is derived from a similar comparative study of the direct and spectral images of the tail of Morehouse's comet. The spectroscopic evidence in that case indicated that practically all the light recorded on the plates was emitted by gaseous particles, yet the direct photographs afforded evidence of the action of light-pressure.

THE DARK BAND SURROUNDING THE POLAR CAPS OF MARS.—Readers of these columns will remember the discussion raised by M. Antoniadi's contention that the dark band seen circling the polar cap on Mars is simply a contrast effect. In support of this contention M. Antoniadi stated (see NATURE, December 23, 1909, vol. lxxxii., p. 227) that photographs of the planet, taken in America, did not show the dark band, although at the same time they showed that the cap was not brighter than the continental areas, and therefore irradiation could not be adduced as the reason for the absence of the band. Prof. Lowell, in a note appearing in No. 4448 of the *Astronomische Nachrichten*, emphatically states that the photographs do show that the polar cap is brighter than the "continents," and actually irradiates in consequence beyond the confines of the disc. Further, the screen through which the photographs were taken was such that the relative brightness of the caps would be considerably modified.

THE SPECTRUM OF NOVA SAGITTARII NO. 2.—The nova recently announced by Mrs. Fleming appears on sixteen photographs taken at Arequipa between March 21 and June 10; the magnitude varied from 7·8 to 8·6 between those dates. The spectrum is quite faint, but shows the hydrogen lines, $H\beta$, $H\gamma$, $H\delta$, $H\epsilon$, $H\zeta$, and $H\eta$, bright; a trace of $H\gamma$ as a dark line is seen on the less refrangible edge of the bright $H\gamma$ line.

The star does not appear on seventeen photographs taken between July 23, 1889, and October 7, 1909, although stars down to magnitude 12·0 are shown on the majority of the plates; one plate shows the fifteenth magnitude or fainter.

A visual observation by Mr. Leon Campbell, using the Harvard 24-inch reflector on October 3, showed the magnitude of the nova to be 10·5.

Prof. Millosevich, on October 15, determined the position, reduced to 1910·0, as 17h. 54m. 26·28s., $-27° 32' 52·1''$, and the magnitude as 10·4 (*Astronomische Nachrichten*, No. 4448).

A NEW VARIABLE STAR OR A NOVA, 97·1910 CYGNI.—In No. 4448 of the *Astronomische Nachrichten* Mr. Hinks records the discovery of what appears to be a new star, or an unrecorded variable, on plates taken by him on August 7, 10, and 12, 1909. The position of the object is R.A. = 19h. 49m. 55·01s., dec. = $+36° 46' 57·4''$ (1900), and the approximate magnitudes on the dates named were 10·4, 10·2, and 10·5 respectively.

Plates taken on August 17, 19, and 26 show no trace of an object in this position, although those of August 17 and 26 show stars down to magnitude 12·5; nor could the star be found visually on September 19 and 26, when it should have been visible if brighter than mag. 13·0.

Mr. Hinks publishes a chart of the region around the object, and asks for any available information as to its appearance on photographs which may have been taken elsewhere.

NEW VARIABLE STARS IN HARVARD MAP, NO. 52.—In Circular No. 162 of the Harvard College Observatory Prof. Pickering announces the discovery, by Miss Cannon, of twenty-two new variable stars on No. 52 of the Harvard maps. The region of the plate is 18h. $-60°$, and altogether thirty-five variables were found. Some of the new variables have ranges of three or four magnitudes, one, D.M. $-57°$ 8613, varying from 7·6 to 10·0; this is of the Algol type, and has a spectrum of the fifth class.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THE Anthropological Section at the Sheffield meeting was presided over by Mr. W. Crooke, whose works dealing with the ethnology of India are well known and highly valued by all anthropologists. His address has already appeared in NATURE (September 29) and need not be alluded to here, except to refer to the tribute that was paid to the work of Dr. Tylor, who has so lately resigned his professorship at Oxford, and who presided over the department (as it then was) of anthropology at the last Sheffield meeting, held thirty-one years ago.

A feature of the section's work was the joint discussion with Section L (Education) on the measurement of intelligence in school children, to which Dr. Spearman, Dr. Lipmann, Dr. Myers, and Messrs. Burt, Brown, and Gray contributed. A report of this discussion will be given in the account of the proceedings in Section L.

Beyond this the work of the section ran on the usual lines, the number of archæological papers being again a prominent feature. The section, as usual, had the advantage of hearing reports on their work by members of the British Schools of Archæology at Athens, Rome, and in Egypt, and also from gentlemen who have been excavating and exploring in the British Isles.

In the following summary the papers are broadly grouped together under the various subjects with which they dealt.

Archaeology.

Mr. T. Ashby described the excavations which have taken place at Caerwent, the site of Venta Silurum. These have consisted of the uncovering of several more houses, and of the excavation of the central insula to the north of the city, which contains the Forum and Basilica. This latter had no apses, and from its S. aisle at each end were entrances into the streets. The Forum was surrounded by an ambulatory and shops. Numerous skeletons were found in another part of the city, but were not contemporary, being obviously of post-Roman date. Closely akin to this paper was Prof. Bosanquet's account of the excavations at Caersws, undertaken by the Liverpool committee for excavation and research in Wales and the Marches.

Mr. H. D. Acland presented a paper on some prehistoric monuments in the Scilly Isles, which consisted of a description of two groups of menhirs. Several of those of one group have a constant orientation differing 4° from a normal bearing. A group of intersecting banks was also described, which have a similar variation as the menhirs.

The excavation of a broch at Cogle, Watten, Caithness, was described by Mr. Alexander Sutherland. The building had been overgrown with vegetation, and five successive layers of ashes and pavement were found. Among the Neolithic remains were several stone pestles, discovered in the lowest stratum; these were of a basalt-like stone and were originally of oval or oblong shape, but had been worn down by constant pounding until some of them had become circular. The broch was 30 feet in diameter.

The Rev. Dr. Irving read a paper on the prehistoric horse, found some little time ago at Bishop's Stortford. Careful comparisons have been made with other skeletons, and the conclusion seems warranted that it represents a late Pleistocene race, which has survived into Neolithic, Bronze, or the Early Iron period, the age of the deposit being

difficult to judge, as stone, bronze, and iron have all been found. The site, however, shows promise of proving to be of some importance, and a committee has been appointed by the association to assist in its examination.

A suggestive paper was contributed by Mr. George Clinch on some unexplored fields in British archæology, in which he directed attention to the amount of destruction of antiquities which is occurring annually, urged the establishment of regular and systematic oversight of great engineering works which involve excavation and removal of soil, and directed attention to certain promising forms of archæological exploration, such as blown sands, peat mosses, marshes, and dried river sites.

The committee appointed to investigate the lake villages in the neighbourhood of Glastonbury reported the results of the work carried out at Meare, on two distinct groups of low circular mounds. The excavations included the examination of three dwellings and trenching with the object of finding the palisading, but although the ground was examined for some 100 feet from the mounds, no such border protection was discovered. The relics found were all of the greatest interest and importance, and show clearly that the Meare people lived under similar physical conditions and civilisation as did their neighbours at Glastonbury.

In what may be termed Mediterranean archæology four papers were presented. Messrs. A. M. Woodward and H. A. Ormerod described a group of prehistoric sites excavated by them in south-west Asia Minor. Nineteen prehistoric mounds were examined, extending from the plains of Elmeli in N.E. Lycia to Lake Kestel in Pisidia. The potsherds found were mainly of a red hand-polished ware, assignable to the Bronze age, but fragments of a black polished ware were also discovered, some of which may possibly be of Neolithic origin. Painted pottery showing affinities to Cappadocian and Early Cypriote Iron age fabrics were also discovered, but this pottery appears to be independent of Ægean influence or importation. The remains of a megalithic rectangular house were found.

A paper on excavations carried out in Thessaly in 1910 was submitted by Messrs. A. J. B. Wace and M. S. Thompson, the sites chosen for the season's work being Tsangli and Rachmani. On the first of these, remains of Neolithic houses were discovered, square in plan with internal buttresses. Celts and vases were found, and also terra-cotta statuettes, of which the male figures, rare in Thessaly, showed markedly phallic characters, while the female were steatopygous.

At Rachmani houses were discovered, and a considerable amount of pottery and a few figurines. A comparison of the two excavations enables the prehistoric age in Thessaly to be divided into four periods:—(1) Neolithic, with red and white painted pottery; (2) Neolithic, with Dhimini and kindred vases; (3) sub-Neolithic, to which period belongs the remarkable encrusted ware; and (4) Chalcolithic, in which period the pottery is unpainted, and the latter part of it is apparently contemporary with Late Minoan II and III.

Dr. T. Ashby, the director of the British School at Rome, described the excavations carried out by him at Hagiar Kim and Mnaidra, Malta, under the auspices of the Maltese Government. The object of the work was to discover whether the excavations carried out many years previously had completely revealed the ground plan and to endeavour to find sufficient pottery to enable the date of the structures to be determined. In both respects the action was justified by results. A large, hitherto unknown, roughly paved area was discovered at both places, and at Mnaidra subsidiary buildings, perhaps devoted to domestic uses, were disclosed. The small objects found, fragments of pottery and flint, corresponded absolutely with those from the hypogeum at Halsaflieni, so that it seems clear that Hagiar Kim and Mnaidra are also of the Neolithic period.

Some cup and ring markings and spirals from the hypogeum at Halsaflieni were described by Dr. Dukinfield Astley. The markings are done in red paint on two of the roofs of the buildings.

Prof. Petrie gave an account of the work carried on by the British School in Egypt at Meydum and Memphis. At the first place the archaic sculptured tombs were removed, owing to the damage they had suffered from native plunderers. Two of these chambers are unique, the colours being inlaid in deep undercut hollows. The burial chamber of the largest tomb was excavated, in which was found a sarcophagus of red granite, the oldest known, dating about fifty years earlier than that in the Great Pyramid. In the course of the work at Meydum quarry marks were found on many of the blocks. As these name the months of quarrying, it makes it possible to fix the shifting months of the Egyptian calendar, as the season of quarrying is closely fixed by the inundation. The result is the fixing of the reign of Sneferu at 3200 or 4700 B.C.

At Memphis work was begun on the temple of Ptah The main result has been the discovery of a large shrine built by Amenhotep III, and a portrait head of King Amasis. Sealings were found on the palace site, while pottery kilns were also carefully explored.

Dr. Seligmann contributed a paper on a Neolithic site in the southern Sudan, at which hammerstones, pygmy implements, and implements of hornstone were found, all on the surface.

A description of the archæological activities in the United States, as carried on by the various universities and public bodies, was given by the well-known American anthropologist, Miss Alice Fletcher, who was appointed a vice-president of the section for the meeting.

Ethnology and Ethnography.

Several papers on general ethnology and ethnography were presented to the section. Mr. E. Torday described the Bu-Shongo of the Congo Free State, a tribe inhabiting the district between the fork of the Kasai and Sankuru rivers. The nation is composed of a number of subtribes all under one paramount chief. The most famous of the chiefs was Shamba Bolongongo, who has become the national hero, and is venerated because he was a man of peace and a great lawgiver and philosopher. The organisation of government now existing is that remodelled by this chief, although it has become greatly weakened. In theory the king is absolute, but his power is limited by two bodies, somewhat analogous to two houses of parliament. Above all is the king's mother. There is a form of totemism. The people are great wood-carvers, amongst the most interesting products of this art being portrait statues of their kings. Five of these are known and three of these are now in the British Museum, amongst these being that of Shamba Bolongongo himself.

Mr. Mervyn W. H. Beech contributed a paper on the Suk of east Africa. These people, who live to the north of Lake Baringo, are akin to the Nandi, but with a large aboriginal element. This is especially seen in their language, which, although it contains a large percentage of Nandi and a little Turkana, has a considerable amount of what is probably aboriginal. The tribe is divided into totemic and exogamous clans, and the social system resembles the Nandi; but, on the other hand, the dress, ornaments, and dances are like those of the Turkana and differ entirely from those of the Nandi.

Mr. G. W. Grabham read a paper on native pottery methods in the Anglo-Egyptian Sudan. He described the various kinds of pots made, the most interesting, perhaps, being the gobanas, or coffee-pots. Two cup-shaped saucers are made and roughly dove-tailed together; the join is then smoothed down, a handle and spout added, and the whole is then scraped, polished, ornamented, and baked.

Dr. W. H. R. Rivers, in his paper on kava drinking in Melanesia, explained that many facts point to this custom being indigenous and not an importation from Polynesia, or, if introduced, that it has a far greater antiquity than other Melanesian customs to which a Polynesian origin has been ascribed. In the southern New Hebrides the method of preparation resembles the Polynesian, and the name is the same, so that here the practice may have been influenced by the Polynesians; but in the northern New Hebrides, Banks and Torres Islands, the name is indigenous, and the whole ceremonial of making and drinking the infusion differs fundamentally from that of Polynesia. In many cases its use has a clearly religious and social character. The occurrence of the practice in the Fly River region of New Guinea suggests that the distribution of the custom may have been very wide, and that in New Guinea and northern Melanesia kava has been replaced by betel.

In his paper entitled "A Search for the Fatherland of the Polynesians," Mr. A. K. Newman endeavoured to prove, partly by the evidence of place names, that the first home of the Polynesians was in the Ganges Valley.

Two papers of general ethnological interest were contributed by Miss Fletcher and Mr. E. S. Hartland. In the former—a sidelight on exogamy—the author directed attention to the exogamic character of the Omaha social organisation, while in the latter Mr. Hartland discussed the origin of mourning dress, and held that mourning was worn not so much as a disguise, as suggested by Dr. Frazer, but as a means of typifying the union of the dead and as an expression of sorrow and abasement, so as to deprecate the malice of a spirit, naturally annoyed at finding itself disembodied.

It is particularly gratifying to record that the committee appointed at Winnipeg to consider the feasibility of starting an ethnographic survey of Canada reported that, owing to representations made by the council of the Association and by a deputation of the committee and others, which waited upon Sir Wilfrid Laurier, the Dominion Government has included in its estimates the sum of 420*l.* to establish a department of ethnology under the Geological Survey. This most gratifying result may be considered as entirely due to the initiative taken by the Association at the Winnipeg meeting.

Two ethnological papers of great interest were those by Prof. Elliott Smith on the people of Egypt, and by Prof. H. J. Fleure and Mr. T. C. James on the people of Cardiganshire. The latter of these should perhaps be classified under physical anthropology, as the survey was largely an anthropometrical one.

Prof. Elliott Smith began by urging the impossibility of reconstructing the history of man in Egypt unless the work is based on the study of physical characters, as apart from mere measurements, of accurately dated human remains from the three great divisions of the Nile Valley—Lower and Upper Egypt and Lower Nubia. Of the origin of the predynastic Egyptians, all that at present could be safely said was that they showed affinities to both the Mediterranean race and to the Arabs. Although just before the end of the predynastic period some slight change in the character of the population can be seen, it is not until the Third Dynasty that the significance of the change can be fully appreciated. At this date it becomes clear that each of the three divisions of Egypt had its own distinctive population: Lower Nubia, a people identical with the predynastic but tinged with negro; Lower Egypt, the descendants of the predynastic peoples, mixed profoundly with white immigrants, who came in by way of the Delta, while Upper Egypt, though not directly affected by either of these alien stocks, was yet indirectly affected by both, through the intermingling of its people with those of the two other districts.

In the time of the Middle Kingdom this white and Nubian influence became more marked in the Thebaid, and thus the gradual gradation of physical characters, from the black of Nubia to the white of the Levantine population in the north, began to set in, a gradation which has persisted to the present day.

Messrs. Fleure and James pointed out in their paper that the basis of the population of Cardiganshire appears to be the Mediterranean type, that is, a type marked by considerable dolichocephaly, dark hair, slight prognathism, and a stature a little below the average. But as the type becomes fairer these marked characteristics disappear, prognathism ceases to exist, and the head becomes shorter. Amongst this population there is also a fair type, in which the heads become still shorter and the stature higher, while the face becomes opisthognathous.

Physical Anthropology.

In purely physical anthropology two papers only were presented, there being still the marked decline in papers of this nature which has been noticeable during the last five years. It is very much to be regretted that the anatomists and other workers in the field of physical anthropology have ceased from presenting the results of their work to the Association, and it is to be hoped that a turn in the opposite direction will soon set in.

Prof. C. J. Patten described a rare form of divided parietal in the cranium of a chimpanzee. Cases of this kind are extremely rare, and the one under consideration appeared to be an example of complete division of both parietals, each by a horizontal suture, running the entire length of the bones and joining the coronal and lambdoid sutures. The case is of further interest owing to the way in which the upper segment of each bone is again subdivided. Correlated with this condition there is a thinning out of the bones of the cranial vault and a reduction in the size and strength of the zygomatic arch and of many of the processes at the base of the skull.

Dr. W. L. H. Duckworth exhibited a microtome, made by the Cambridge Scientific Instrument Company, which provides a means of preparation of anthropological material possessing great interest. Some of the preparations thus made were mounted as lantern-slides and exhibited; for example, in a section of the leg of an adult man, tissues so distinct in consistency as bone, tendons, and muscles could be seen. Other specimens exhibited were sections of the larynx and tongue.

Finally, the report of the committee to conduct archæological and ethnological researches in Crete contained long reports on Cretan anthropology, by Mr. C. H. Hawes, and physical observations, viz., head form and pigmentation, of Cretan school children, by Dr. Duckworth. Both these reports contained a mass of detailed measurements and observations which it is impossible to summarise. One point may, however, be mentioned. Dr. Duckworth is of opinion that the general physique of Cretan children is frequently, if not always, poor, being markedly inferior to that of British children of the same age.

AGRICULTURE AT THE BRITISH ASSOCIATION.

IN drawing up the programme for the Sheffield meeting the organising committee of the Agricultural Subsection adhered to the lines laid down last year. Certain problems of current interest and importance were discussed at joint meetings so far as possible, and attention was directed particularly to those aspects of the problems on which men of pure science could throw much needed light. There were, therefore, very few general papers, and such as were read were regarded rather as preliminary accounts of work that must come on later for discussion.

The chairman's address has already been printed *in extenso* in these columns (September 8). It dealt with fertility, the eternal and fundamental problem in agriculture, and traced the history of the views that have been held since the early experimenters of the seventeenth century began their work. Fertility depends on several factors, any one of which may at a given time become a limiting factor and determine the growth of the plant. The amount of available mineral food, the supply of water, and the supply of nitrates all enter into the problem. All that science can do as yet is to ascertain the existence of these factors one by one, and bring them successively under control; it is not yet possible to disentangle all the interacting forces the resultant of which is represented by the crop.

Dr. Crowther and Mr. Ruston discussed the impurities of the town atmosphere and their effect on vegetation. Rain water falling within the industrial section of Leeds is highly charged with mineral and tarry matter, and also contains a good deal of acid. The rain of the residential districts is much purer, but still not as pure as country rain. Pot experiments, and observations made in gardens, parks, &c., showed that the effect of the impurity was complex; the stomata of the plants were blocked, especially if they happened to be sunk as in the conifers; the soil also suffered. These actions produced marked results on vegetation; in extreme cases the plants were actually killed, and even those surviving were much affected. The case of grass was examined in some detail because of its technical importance. It was found that the impure rain reduced the yield and the protein-content of the herbage but increased its fibre-content. The feeding value was therefore much diminished.

Prof. Berry followed with an account of the ether extract of the oat kernel. It has long been known in a general way that the ether extract is not all fat, although so labelled as a matter of convenience. Prof. Berry has

examined the extract in detail, and the great value of his work is that he is dealing with definite varieties of oats grown under known conditions. It is understood that the research is being continued, and some interesting conclusions may be looked for.

Mr. A. S. Horne gave an account, illustrated by photographs, of a bacterial disease of potatoes. Not long ago it was supposed that plant diseases were caused by fungi, but cases are steadily accumulating where bacteria are the active agents. Several cases have been worked out at Newcastle, and it was felt that on a future occasion more time will have to be devoted to this important branch of study.

The second day was given up to a discussion of two subjects now coming much into prominence. Sugar-beet growing was dealt with by Mr. Sigmund Stein and Mr. G. L. Courthope, M.P. Later in the day nitrogen fixation was discussed by Mr. Golding and Prof. Bottomley. It has always been known that sugar beet could be grown in England, but the industry never had an opportunity of development by reason of the Continental sugar bounties. The Brussels Convention, however, has so altered the position of affairs that a reasonable prospect of success seems assured; already factories are springing up in different parts of the country, and farmers are contracting to supply the necessary beets. For many years Mr. Stein has advocated beet-sugar production, and in his paper he gave a summary of the various experiments he has made to meet the objections that have from time to time been raised. He claimed that the practical difficulties, both in the field and the factory, are now overcome, and the time is ripe for active development. Mr. Courthope dealt with the financial aspects of the question, and gave a number of carefully prepared statistics showing that the new industry has every probability of success. This paper created a very favourable impression, and the speakers that followed agreed that a good case had been made out. There has, as usual, been a good deal of exaggeration about the possible effect of a new rural industry. If sugar beet is grown, some other crop will have to go out; the gain to the country will therefore be the difference between the new and the old, and not, as is commonly stated, the whole amount that the new crop will bring in. Still, there is no doubt that a new industry and a new market would have a useful steadying effect on agricultural prices.

Nitrogen fixation was the next subject. Prof. Bottomley brought forward the evidence in favour of his proposition that Azotobacter, in conjunction with Pseudomonas, both obtained from the root tubercles of Cycas, will "fix" more nitrogen than either alone. He further argues that this mixed culture will grow in soils and "fix" nitrogen to form compounds readily transformable into plant food. Some discussion arose as to the interpretation of the results; the quantities involved are small, and the experimental errors known to be considerable. The great difficulty arises, however, in the absence of a satisfactory standard by which one experiment may be compared with another.

Mr. Golding dealt with his subject in a more general way, his researches having been directed to the whole question of nitrogen fixation in the root nodules of leguminous plants. This fixation is brought about by bacteria which invade the root hair as infection threads, pass through a rod-shaped stage, and finally assume the bacteroid (Y) form. Mr. Golding is steadily overcoming the difficulties of working with the organism in artificial media, and is succeeding in making it pass through the changes that it undergoes in the plant. During the period of active nitrogen assimilation an alkaline substance is formed; after a time, if the products are not removed, assimilation stops, the alkali disappears, and the medium becomes acid. Dr. Russell pointed out that this change from alkaline to acid reaction indicated that the organisms were now utilising the nitrogenous base already formed, and therefore setting the acid free, a change known to go on in other cases.

On Monday, September 5, a joint meeting was held with the Zoological Section to discuss the effect of partial sterilisation of soils. Dr. Russell read a paper which he and Dr. Hutchinson had prepared, giving an account of the work they have been doing at Rothamsted during the past three years. There is a notable increase in productiveness when a soil is heated or treated with volatile antiseptics like toluene. This was traced to an increase in bacterial activity, which, in turn, was shown to be the result of removing some factor that had in the original soil limited bacterial activity. By drawing up a systematic plan of experiment it was possible to find what processes would, and what would not, put the injurious factor out of action, and so the authors had arrived at a list of properties the factor possessed. According to their results it appears to be a living organism larger than bacteria, but developing more slowly, killed at or below 50° or by prolonged drought. It might actively destroy bacteria, or, on the other hand, it might form a protoplasmic layer round the soil particles containing organic matter, and thus keep off and starve the bacteria. The zoologists present made some very useful suggestions. Dr. Shipley recommended sewage-farm soils as the best place to start hunting for the organism. Dr. Ashworth suggested that the amœbæ or amœboid organisms of the soil might be the culprits, and considered that methods of investigation like those used by Musgrave and Clegg or by Noc might with advantage be tried. Mr. T. J. Evans, on the other hand, thought that the results indicated a mycetozoan plasmodium, while Mr. J. J. Lister urged that mycetozoa would require vegetable matter, which, however, they would have in the soil.

Mr. K. J. J. Mackenzie followed with an account of the "points" prized by the breeder of high-class stock, and gave the results of measurements he had made to find out how far the "points" really are correlated with the characters they are supposed to indicate. So far as he has gone—he is pursuing the problem further—the correlation is very slight, and it can only be inferred that the breeder arrives at his eminently successful results rather by an intuitive process than by any use of his "points." The question is of great economic importance, because England is, and seems likely to remain, the stud-farm of the world.

A joint meeting with the Geological Section followed, at which soil surveys were discussed. A paper by Mr. Hall and Dr. Russell was read, dealing with the objects and methods of agricultural soil surveys. The ordinary drift map is not sufficient, although it makes an admirable starting point. It is necessary to classify the soils further, to study them in their relation to the local agriculture, and to ascertain the effect of manures, of rainfall, topographical position, &c. Illustrations were given to show that a soil may be sufficiently described from the agricultural point of view when its mechanical analysis, and its positions on the geological, orographical, and rainfall maps are known. Mr. L. F. Newman gave a preliminary account of his survey of the drift soils of Norfolk, which seems to indicate a fairly regular distribution of the various types of soil. Mr. C. T. Gimingham described the "teart" land of Somerset, on which animals "scour" badly. This condition is confined to one formation, the lower lias, and disappears when even the most superficial covering of alluvium occurs. A large acreage is affected. Evidence is adduced that the cause is to be sought in the physical state of the soil; if this is so, it should be capable of remedy. It is much to be hoped that the field trials which Mr. Gimingham has drawn up to test this view will be carried out.

The last day opened with a paper by Mr. Hall on the cost of a day's horse labour on the farm. This fundamental problem of agricultural economics has been but little investigated, and Mr. Hall's estimate of 2*s.* 7*d.* per day must be regarded as the most complete we have at present. Another economic paper followed, by Mr. Turnor, on costs in the Danish system of dairy farming. The data were gathered during a tour of Denmark, and represent a good deal of study of the subject. Mr. Turner is shortly bringing out a book in which the results of his investigations will be more fully dealt with.

The rest of the day was devoted to a discussion jointly with the Economic Section of the errors of agricultural experiments. Prof. Wood opened the subject with three papers prepared in conjunction with Messrs. Stratton and Bruce. From the results it appears that many of the feeding trials carried out in the country are of very doubtful value. Agriculturalists have usually neglected the experimental error; in few, if any, of the numerous county council experiments, for instance, is it ever taken into account. Prof. Wood's papers, along with one by Mr. Hall and Dr. Russell on field trials, have emphasised the import-

ance of the matter, and steps are being taken to distribute these papers among agricultural experimenters.

A paper by Mr. Collins on the errors of milk analysis concluded the session.

The position of agriculture at the British Association is not yet settled. Whatever the council decide to do, it is hoped they will continue to give a separate organisation to agriculture, and thus afford to workers in agricultural science an opportunity—the only opportunity for some of them—of meeting their fellow workers in pure science and discussing their problems. It is necessary to get help from several sides and not simply from one, as from the chemical or the botanical, which seems to be the theory of a sub-section. However, whether lawfully or not (it appears to have been unlawfully) the organising committee has hitherto enjoyed the fullest liberty, and has succeeded in arranging a series of meetings that have proved extremely helpful to agricultural investigators, and promise to play no small part in the encouragement of agricultural research.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

IN addition to the presidential address, which has appeared already in NATURE, there were a number of interesting papers communicated to the section. Physiology was unique in that it was the only section that met at the University; and thus, although somewhat isolated from the other sections, enjoyed the advantage of the laboratories for demonstrations.

There were two joint meetings, one with Chemistry (Section B) and Botany (Section K) on the biochemistry of respiration, and the other with Education (Section L) on speech; the latter will be reviewed in the proceedings of the section of Educational Science. In addition, Dr. Leonard Hill, F.R.S., gave an interesting address on the prevention of caisson disease. The individual papers will be reviewed, as much as possible, so as to form groups in a logical sequence.

The discussion on respiration, held in the meeting-room of Section K, was opened by Dr. F. F. Blackman, F.R.S., who dealt with the subject under three headings.

(1) The series of chemical reaction which take place during oxidation. He took glucose as a typical example, of which the final products are carbon dioxide and water, but the intermediate steps are difficult to follow. Buchner's zymase produces alcohol and carbon dioxide from glucose, but it has been shown that alcohol cannot be oxidised by plants, and hence it must be surmised that some other substance, before the breakdown has reached the alcohol stage, is what is actually oxidised. There are probably many of these fugitive compounds, amongst which may occur lactic acid and di-hydroxy acetone. An alkaline sugar solution, as the result of exposure to sunlight, gives rise to substances which are easily oxidised. He then dealt briefly with oxidases, peroxide formation, and Palladin's hypothesis of respiratory chromogens, which are oxidised by oxidases to peroxides, and then pass on the oxygen to oxidisable material.

(2) The physical chemistry of the processes involved in oxidation. Influence of temperature on velocity of reaction (usually shows a coefficient of about 2·5 within the limits of temperature at which living processes can occur); the uniformity of the respiratory quotient (O_2/CO_2) at different temperatures and the effect of the concentration of the reacting substances were discussed. He illustrated these points by referring to his experiments with green leaves and potatoes (starchy and rich in sugar). The output of carbon dioxide by green leaves is reduced to zero by exposure to sunlight. The potatoes rich in sugar show a greater rate of oxidation than the starchy ones. The conclusion is arrived at that there is a minimal tissue respiration and an excess of respiration depending on the supply of respirable material.

The influence of accelerators, paralysators, and other substances was mentioned.

(3) Special influences of colloidal nature of cell protoplasm. Oxidation and reduction take place side by side, and death of the cell mixes up these two processes. Alterations of permeability of protoplasmic septa may account for changes in physiological oxidation processes.

Dr. H. M. Vernon referred to Dakin's work on oxidation of fatty acids and amino-acids by hydrogen peroxide and traces of ferrous salts. If zymase is allowed to act upon glucose for a short time, then the solution is boiled and oxidase and hydrogen peroxide are added, there is almost complete oxidation to carbon dioxide and water; this suggests that oxidases may act in living cells if organic peroxides can replace hydrogen peroxide. His own experiments on survival respiration (kidney) point to the presence of oxidases, and that certain poisons act by combining with aldehyde or similar groups. Some substances act especially on the "high-grade" process (formation of carbon dioxide) and not so much on the "low-grade" process (oxygen absorption), and thus the respiratory quotient is lowered. In relation to minimal protoplasmic and excess respiration, he directed attention to the fact that minced tissues show at first a greater output of carbon dioxide than when intact, but that the respiration soon falls to a much lower level.

Dr. E. F. Armstrong pointed out that in many respects oxidases differed from the other kinds of enzymes (they are heat stable and not specific in action), that their action can be imitated by colloidal suspensions of inorganic matter, and that traces of inorganic material are usually present in them. There are, however, specific oxidases. He then demonstrated the blackening of laurel leaves by the action of toluol (other chemically inert substances with little affinity for water act similarly), which he ascribed to a general breakdown of the protoplasm with liberation of oxidases.

Mr. D. Thoday spoke about the result of experiments on anæsthetised leaves. Small doses of chloroform cause a temporary increase of oxidation. A large dose causes a diminution in the output of carbon dioxide; with Helianthus and cherry laurel there is a great increase in oxygen intake, which quickly falls off, but with Tropæolum the oxygen intake falls at once. It was suggested that tannins oxidise first, and as there are no tannins in Tropæolum there is no initial increase of oxidation. Probably the result is brought about by an increase of permeability.

Prof. H. E. Armstrong, F.R.S., referred to Leathes' work on the splitting of fats at intermediate points in the carbon chain, and to the formation of peroxides by manganese and iron with hydroxy-acids. Oxidation may take place by decomposing water with liberation of hydrogen; in plants the hydrogen may be used to reduce carbon dioxide to formaldehyde. The leaf surfaces show a permeability similar to that found by Adrian Brown for barley grains.

Prof. Waller and Dr. Reynolds Green spoke, and Dr. Blackman replied.

Dr. Leonard Hill, F.R.S., reviewed the work done in relation to the prevention of compressed air illness. Whilst exposed to high pressure the body dissolves a larger amount of gas than at ordinary atmospheric pressure, and when the pressure is reduced bubbles of gas may be set free in the blood vessels. The solubility of the gas follows Henry's law; owing to the capacity of the tissues to absorb oxygen it is only the nitrogen that is set free in the vessels. The symptoms depend on the portion of the circulation which is stopped by the nitrogen embolus. Different portions of the body saturate at different rates, but work, by increasing the circulation, increases the rapidity with which the body takes up and gives off nitrogen. By analysis of the gases in urine it can be shown that it takes an appreciable time for the body to get into equilibrium with the pressure of the nitrogen in the atmosphere, or, in other words, the blood does not get into equilibrium with the gas on passing once through the lungs.

The relative merits of uniform decompression and decompression by stages were discussed. Long shifts are better than short, as there are fewer decompressions for the same amount of work, and the danger is due to decompression. When symptoms occur they can be abolished, or the danger minimised by recompression to the original pressure.

He recommended that, during decompression, occasional inhalations of oxygen should be taken (to lower the partial pressure of the nitrogen in the lungs, and thus

hasten the removal of nitrogen from the blood) and that exercise should be taken to increase the circulation, and thus remove the nitrogen from the "slow" parts more quickly.

Prof. F. S. Lee, of Columbia University, read two papers. (*a*) "The Cause of the Treppe." During the course of the staircase the excitability of the muscle increases. Clamping the trachea causes a second treppe. Fröhlich states that the treppe is due to slowing of relaxation, so that the increase in height of contraction is only apparent, as the contraction starts at a higher level; but at one stage of the treppe the contractions are not prolonged, while there is no delayed relaxation during fatigue of mammalian muscle. (*b*) "Summation of Stimuli," with Dr. M. Morse. Repeated subminimal stimuli can cause contraction. Traces of lactic acid, carbon dioxide, and other substances that are formed during fatigue increase the excitability of muscle. Gotschlich finds that muscle becomes acid as the result of repeated subminimal stimuli. Prof. Lee suggested that the treppe and summation of stimuli are both due to traces of fatigue substances.

Prof. C. S. Sherrington and Miss S. C. M. Sowton presented two communications dealing with the constant current as a stimulus of reflex action, and the effect of the intensity of the current on the response to stimulation. The preparation used was the isolated extensor of the knee in decerebrate rigidity. Non-polarisable electrodes were placed on an afferent nerve of the limb. A weak stimulation caused a reflex increase of tonus. This is a nearer approximation to the artificial production of reflex tonus than has hitherto been obtained. Otherwise the result of artificial stimulation is a reflex inhibition, as indeed it is with this stimulus when stronger. A stronger stimulus causes an increase of tone, followed by inhibition. A strong stimulus abolishes the preliminary increase of tone, and only inhibition results. In fact, the results obtained are exactly the same as have long been known for the direct stimulation of the opening muscle of Astacus claw. Stimulation occurs at the make and break of the constant current, and not usually during its passage. With a strength of current which gives a reflex increase of tone, chloroform converts the response to inhibition, and as the chloroform passes off the response to the stimulus again becomes an increase of tone.

Dr. J. Tait: (1) "The Conditions Necessary for Tetanus of the Heart." Refractory period of heart consists of absolute and relative refractory stages. The former lasts during systole, and the latter gradually diminishes from the end of systole. The stronger the stimulus the earlier it can be made effective in the relative refractory period. If the stimuli are sufficiently strong they can be effective at the end of systole, and tetanus results. Very strong stimulation causes electrolysis, which produces a series of contractions that gradually die away. (2) "Neurogenic Origin of Normal Heart Stimulus." Excised frog's heart-beat sometimes shows grouped beats (Luciana groups). These are probably due to waves of excitation from rhythm-producing centre. The tendency to grouped beats is increased by lack of oxygen, and the rate and rhythm correspond to that seen in tracings of Cheyne-Stokes respiration; hence the normal heart-beat is regulated by some mechanism similar to that which is affected in Cheyne-Stokes respiration. A constant stimulus with waves of increasing and diminishing strength would, as the strength increased, become effective earlier in the relative refractory period, and hence the increase of rate of beat.

Dr. H. M. Vernon reported the results of some experiments on the combination of poisons with the contractile substance of cardiac muscle. He used the tortoise heart, and perfused it with the various solutions. Alcohol, chloroform, and ether all cause effects proportional to their concentration, and recovery occurs on removal of the drug by fresh saline. Hydrocyanic acid and sodium fluoride cause a marked effect in small concentrations, but the action does not increase much when the strength of solution is increased. Recovery is not good, and is less with the stronger strengths. On removal of the sodium fluoride the heart-beats show remarkable oscillations of amplitude. The vitality of the heart is always permanently injured, as a second test with the same strength causes a greater effect than at first. The season and condition of the heart cause minor differences in the result.

Prof. C. S. Minot, of Harvard University, gave his views on the morphology and nomenclature of blood corpuscles. Present nomenclature not satisfactory. Both red and white cells originate from the primitive wandering cells (mesamœboid). Leucocyte = white cell, and can be subdivided into lymphocyte (young leucocyte), finely granular, and coarsely granular. Erythrocyte = red cell, and they can be subdivided into ichthyoid stage (cells like those in fish with a nucleus showing chromatin network), sauroid stage (like birds and reptiles, nucleus homogeneous, usually called normoblast), and plastid (non-nucleated or mammalian type).

Prof. C. S. Sherrington, F.R.S., Dr. E. E. Laslett, and Miss F. Tozer communicated the results of some experiments indicating the existence of afferent nerves in the eye muscles. The sensory nerve-endings maintain a primitive reptilian type; many "brush" and "creeper" endings are found in the region where muscle and tendon join. No muscle-spindles are found, but a clasping form of ending, which is probably a simple form of spindle. The eye muscles have a greater nerve supply than any other muscles. By cutting the nerves and examining the muscles after the nerves had degenerated it was proved that the third, fourth, and sixth cranial nerves contain sensory fibres in addition to the motor fibres, which are usually stated to be the only kind present. These nerves are therefore afferent-efferent nerves. No sensory fibres to the extrinsic eye muscles were traceable from the first division of the fifth nerve. There are a few small medullated nerve-fibres which do not degenerate after section of all of the foregoing nerves; these are apparently vasomotor, and come from the otic ganglion.

Dr. Dawson Turner and Dr. T. George recorded the results of the X-rays in therapeutic doses on the growing brains of rabbits. The development of the exposed side of the brain was slower than the other side. Fatty degeneration of the irides and loss of weight occurred during treatment. The subject is important, as X-rays are frequently used on children in the treatment of ringworm.

Prof. A. B. Macallum, F.R.S., read three papers: "The Origin of the Inorganic Composition of the Blood Plasma," "The Inorganic Composition of the Blood Plasma in the Frog after a Long Period of Inanition," and "The Microchemistry of the Spermatic Elements in Vertebrates."

The first two deal with the relative amounts of the inorganic salts in the blood. The ratios of these to each other are fairly constant throughout, and agree with the relative amounts of the same substances in sea-water; but there are some variations, and the total amounts of inorganic material are different in the different species. He explains the distribution of the salts as reflecting the composition of the ocean at that epoch when the blood plasma of the species in question ceased to respond to changes in the salts of the ocean. The vertebrate kidney is the factor that maintains the ancestral composition of the blood.

The third paper dealt with the distribution of iron and potassium in the spermatic elements. The iron in the nucleus diminishes through the series spermatogonia, spermatocyst, spermatid, and is absent from the head of the sperm itself. Mode of elimination masked. Potassium abundant in spermatic elements, gathered at anterior and posterior ends in frog, and only in posterior region and in bands in man. No potassium in the head itself.

Prof. W. H. Thompson spoke on the nutritive value of beef extract. Dogs were fed on a constant amount of dog biscuit until their weight was steady. The addition of beef extract caused an increase of weight ten or twenty times as great as the amount of extract added. Boiled egg-white was not nearly so efficacious. Nitrogen apparently not retained, and when beef extract was discontinued the dogs returned to their former weight. The increase in weight is not due to retained water, but to an increased digestion and absorption of the dog biscuits, as the nitrogen and total amount of fæces were diminished.

The reports of research committees were, as usual, of a technical nature. They often briefly referred to papers which have been published elsewhere, and thus are not suited for detailed description here. Arising out of the report on anæsthetics was a brief discussion on the advisability of legislation to improve the training of those who are destined to administer anæsthetics, and to prohibit unqualified persons from administering them. Prof. A. D. Waller, F.R.S., in connection with the report on electromotive phenomena in plants, read a paper describing the method used to estimate hydrocyanic acid in plants and animals, with an application of the method to medicolegal purposes. The committee on ductless glands report on a considerable number of researches, the results of some of which have already appeared. The reports on body metabolism in cancer and on mental and muscular fatigue each contain instructive and suggestive material.

Some interesting photomicrographs of muscle fibres were shown by Dr. Murray Dobie, who published his first paper on the structure of muscle in 1848.

Prof. J. S. Macdonald exhibited the respiration calorimeter on two separate occasions. The heat production of a resting man was compared with that of a man riding a bicycle.

A SUGGESTED RESEARCH FUND FOR TROPICAL DISEASES.

THE *Times* of November 2 publishes the subjoined appeal which Lord Northcote has addressed to the Lord Mayor in favour of the allocation of a part of the fund raised for a London memorial to the late King to the establishment of an Edward VII. Tropical Research Fund. The proposal has received the support of leading representatives of many national interests, including Lord Crewe, Secretary of State for the Colonies, Lord Elgin, Lord Kitchener, and Mr. Joseph Chamberlain.

Letter to the Lord Mayor.

My Lord Mayor,—Having noted that you are taking steps to form a representative Mansion House Committee for the purpose of raising a fund to provide a memorial of the late King in London, and that you are receiving numerous suggestions as to the form which that memorial should take, we desire respectfully to offer the following suggestion for your earnest consideration.

(2) The late King, in his beneficent activity for the welfare of his people, was inspired by two ideals—peace for mankind and war on disease. His work in the former of these directions has been recognised by the world at large; it is in following his lead in the second that we think that a fitting tribute to his memory will be found.

(3) Only recently, but now unmistakably, has the nation become alive to the vital importance of its tropical possessions. Their development proceeds apace, but at a heavy cost in human life and vital energy. Rarely does a mail arrive which does not bring sorrow into at least one home in these islands.

(4) For generations mankind have been willing to accept in a fatalistic spirit the death toll levied upon them by what was vaguely known as "the climate." Now this is no longer so. Thanks to the devoted labours of scientific men—among whom our own countrymen hold an honoured place—we know in many instances what the enemy is and how it is to be met.

(5) Those who are not conversant with the subject will be surprised and almost startled to hear the effect on human life of measures taken as the result of such investigations. We give three illustrations, drawn from the history of three of the greatest scourges of the tropics:—

(*a*) Malaria.—In Klang and Port Swettenham, two towns within the protected Federated Malay States, remedial measures were commenced in 1901. The deaths from malaria were in 1901 368 and in 1905 45. In the surrounding districts, where no measures were taken, the deaths for these years were respectively 266 and 351. In Hong Kong remedial measures were commenced in 1901. In that year the admissions to hospital were 1294 and the deaths 132. In 1905 the admissions were 419 and the deaths 54. In 1904 the United States took over the administration of the zone of the Panama Canal; the deaths from malaria, which in 1906 were 821, had sunk in 1908 to 282.

(*b*) Yellow Fever.—In the city of Havana 35,952 persons perished of yellow fever between 1853 and 1900. The United States Government commenced remedial measures in 1900, and in 1907 only one case of yellow fever was reported.

(*c*) During the last three years steps have been taken in Uganda to stamp out sleeping sickness, an epidemic which in one district alone had destroyed some 200,000 people out of a total population of 300,000. In 1907 the deaths in the kingdom of Uganda numbered less than 4000, and in 1908 they fell to 1700.

(6) It will be seen that, tested by results, these figures are full of promise, and prove conclusively that the measures taken have proceeded on sound lines.

(7) It will naturally be asked: How have these results been achieved? The answer, so far as this country is concerned, is by private effort in close cooperation with the Government. Leaving out of account the Liverpool School of Tropical Medicine, which has been generously endowed by the citizens of that city, the bodies which are responsible for sustained and organised effort are the Royal Society, the London School of Tropical Medicine, the Sleeping Sickness Bureau, and the African Entomological Research Committee, all of which are associated with the metropolis. The first of these enjoys no direct Government support, and has carried out its work by a committee which includes some of the most eminent names in the profession of tropical medicine, who have given their services freely and gratuitously. The London School of Tropical Medicine at the Albert Dock, which owes its establishment, in part, to private generosity, receives an annual grant from Government of 1300*l*. The Sleeping Sickness Bureau is supported entirely by Government, the annual cost being some 1200*l*. The African Entomological Research Committee has recently been established to investigate the insects which convey disease to men, animals, and plants in the tropics, and includes among its members the best authorities on the subject. It receives a Government grant of 2000*l*. a year, and it is working in close cooperation with the Natural History Museum. In addition to the foregoing grants, a grant of 750*l*. a year is made to the University of London for the purpose of assisting work which has an important bearing on tropical medicine.

(8) The three cases which we have mentioned above are those in which the most striking results of scientific research have hitherto been obtained, but it is hardly necessary to say that they cover only a small portion of the field. Notwithstanding the rapid advance of knowledge in tropical diseases, there are many as yet unknown or imperfectly understood. The causation of blackwater fever, of dengue, of beri-beri, and of many other diseases still calls for investigation.

(9) We submit to your committee that no more appropriate memorial to our late Sovereign could be proposed than the establishment of a fund to carry on and extend the work of research into tropical disease. We further submit that it is eminently appropriate that London, the metropolis of the Empire, should take the lead in a movement for giving the full benefit of British administration to these outlying portions of the King's dominion, which have contributed in no small measure to her prosperity in the past, and will, by their development, give still ampler ground for her gratitude in the future.

(10) There can be no class in this great city to which the scheme will not appeal. To the rulers, the missionaries, the philanthropists, and all those who concern themselves with the welfare of the millions of coloured races whom Providence has committed to our charge it will appear of transcendent importance. To those whose kith and kin have gone out to bear their part in the work of civilising our tropical possessions, in whatever station of life, it will appeal no less strongly. To the man of business, in whose profit and loss account the dangers to the health of his employés figure so largely, our proposal will need no further recommendation. The ultimate aim is the creation of a Tropical Britain whose peoples are freed from the scourge of sickness, and where

the work of civilisation moves forward without the present toll of life and health. It is impossible to overestimate the results, both moral and material, that such a consummation would entail.

(11) We suggest that a fund should be established—to be known as the Edward VII. Tropical Research Fund—the interest of which should be devoted to furthering the objects which we have indicated. We think that the cause which we have at heart will be best served by not attempting to define too strictly the way in which this revenue should be appropriated. It is probable that in the first instance, and to a large extent, it would be most usefully expended in subsidising the efforts of the institutions to which we have already referred, being administered by a body whose composition will be a guarantee to the subscribers that their moneys are being wisely and economically applied.

We are, my Lord Mayor, yours faithfully,

NORTHCOTE.

25 St. James's Place, S.W., October 27.

MODERN SCIENTIFIC RESEARCH.[1]

RESEARCH is a word much used in newspapers and in public discussions nowadays, but few people outside purely scientific circles have any clear idea as to its meaning. Of course, the dictionary tells us that it signifies a searching again or a careful search, but the question then arises, What is the object of the search and are there any rules to guide?

The object may be purely visionary, as was the object of the early chemists and alchemists, whose operations, extending through the dark centuries of the Middle Ages, left behind practically nothing but an extensive, though barren, literature, the witness of the credulity and ignorance of those times. The lesson to be derived from the whole of this strange history is one which needs to be continually revived and set in the new light of modern discovery and invention. The lesson is simply that until men began to observe and interrogate nature for the sake of learning her ways, and without concentrating their attention on the expectation of useful applications of such knowledge, little or no progress was made. In other words, until a sufficient foundation of pure science has been successfully laid there can be no applied science. Real progress comes from the pursuit of knowledge for its own sake.

I say, again, this truth needs to be continually reiterated, for there are still too many people who think that the true and only business of science is to find out useful things, and who regard all the rest as waste of time.

The first qualification for research is undoubtedly that kind of inspired curiosity which can never be eradicated, and which we know by many examples is not defeated by such obstacles as poverty, or ill-health, or pressure of other necessary occupations. Another qualification is some knowledge of the subject chosen for inquiry. As to this latter qualification considerable differences of opinion have been expressed. Priestley, whose statue stands near the Town Hall in Birmingham, and many of the chemists of his time, had very little preparatory instruction, but some of them made discoveries of fundamental importance. Priestley seems to have been of opinion that very little preparation is necessary, and the discoveries which might result from experiment were regarded by him as largely the result of chance and to be compared with the game which might fall to the gun of a sportsman in a new country, and whether fur or feather cannot be foretold. But though this might have been partly true in Priestley's time, it is certainly very far from true in our day, when the accumulation of knowledge, however imperfect, is still immense.

Every great discovery is the culmination of a long series of discoveries each of which is a necessary step, and ignorance of these preliminaries stands in the way of advance.

It will be worth while to examine a few cases by way of illustration. No better example can be found than the establishment of the great principle in chemistry commonly called the periodic law. According to this law, the properties of the elements and of their compounds stand in a definite relation to their atomic weights.

Modern views concerning the constitution of gases affords another illustration of the way in which the possession of one kind of knowledge leads to more knowledge. Forty years ago students were led to believe that there were two kinds of gases, namely, on the one hand, those which by the action of cold, or pressure, or both together could be liquefied, and on the other hand some half a dozen which could not be reduced to the liquid state. This was attributed to some fundamental difference of constitution in the two kinds of gas.

If we look for an example drawn from the domain of biology there is the doctrine of evolution, now universally accepted, which is based on the results of the patient collection of facts by Darwin and Wallace. But those facts would perhaps not have been collected, and they would certainly have been without meaning, but for the results of the study of comparative anatomy by previous generations of naturalists and palæontologists, as well as the recognition of the great doctrine of uniformitarianism in geology proclaimed and established by Lyell.

The examples cited will not appeal to the practical man in the same way as some instance taken from a direct application of science to business or practical affairs. If it is really necessary to consider a case of that sort, nothing could be better than the *dynamo*, which, as a transformer of energy, comes into prominent daily use in connection with lighting, traction, and as a general motive agent. The detailed history of the evolution of the dynamo would be a long story, and on this occasion it is only necessary to point out one or two facts. For the fundamental principles involved we must go back to Benjamin Franklin, and Galvani and Volta, all in the eighteenth century, and later to 1831, when Faraday discovered the generation of induced currents by moving a conductor in a magnetic field. But doubtless the experiments made by Franklin with the kite, by Galvani on frogs' legs, and by Volta and Faraday with bits of wire, were by the people of their day looked upon with a mixture of amusement and contempt, just as some people even at the present time are apt to exclaim, "Who cares whether there is oxygen in the sun?"

It is obvious, then, that whatever may have been possible in Priestley's time, the wholly uninstructed person cannot expect to meet with much success in these days in the discovery of new facts; and although the exceptional man may acquire in a very short time some knowledge of a special part of a subject, he is in perpetual danger of falling into great mistakes. It seems to me that a considerable amount of knowledge, skill, and experience is an indispensable equipment for anyone who enters seriously into the practice of scientific research. Not that these qualifications alone serve as inducements to such a career, for it would be quite easy to point to examples of learned people who have added nothing new to the branch of knowledge with which they are best acquainted. This is not necessarily due to indolence, nor to ignorance of the methods of research, but is merely the result of peculiarity of temperament which lacks that divine curiosity which alone supplies the stimulus.

I am speaking now only of real scientific research, the inquiry into the secrets of nature, not of the occupation of those who have only practical ends in view.

Looking back over the great principles of natural science, we see that in every case they have been established by the efforts of the amateur, and by amateur I mean all who have undertaken the work for the pure love of it. This includes, not only men of independent position like Cavendish, Lyell, and Darwin, but a large number of men who have held the office of professor or teacher, but who, in this country at any rate, are neither paid to do such work nor required by the conditions of their appointments to undertake it. So far as I know, there is but one institution in this country in which the professors are not required to teach, but only to press forward into the unknown, and that is the Royal Institution in London. But the character which that famous place has assumed during the last hundred years is not that with which it began its career. It was started at the end of the eighteenth century by Count Rumford with purely utilitarian purposes in view, namely, for teaching the

[1] Presidential address delivered to the Vesey Club, Sutton Coldfield, on October 13, by Sir William A. Tilden, F.R.S.

applications of new discoveries in science to the improvement of arts and manufactures and to "facilitating the means of procuring the comforts and conveniences of life"; and while retaining that character and those pretensions it soon came to the verge of collapse. But Davy's lectures and discoveries changed all that, and Faraday's genius consecrated the laboratories for all time to the service of pure science.

Let us review very briefly the great principles on which physical science is based.

First, of course, there are the fundamental principles of the conservation of matter and of energy, the latter finally established on a quantitative basis by Joule in 1843. There is the principle of uniformitarianism introduced into geology by Lyell now extended so as to include, not only the phenomena of this earth, but of the whole cosmos, such extension being mainly due to the use of the spectroscope by Kirchoff and Bunsen, and only a little later by Huggins. The principle embodied in the so-called periodic law of the elements, already referred to, has led to a general belief in the evolution of matter from one primary material, and physicists and chemists are vying with each other in the endeavour to gain evidence as to the details of the process. I need scarcely say that the principle of evolution as applied to living beings is associated indissolubly with the names of Darwin and Wallace.

Notwithstanding the discovery of radium and its allies, and the discoveries by J. J. Thomson as to the disintegration of atoms into corpuscles a thousand or more times smaller, all ordinary chemistry is built up on the conception of atoms introduced by John Dalton just a hundred years ago. The consolidation of this theory has proceeded as a consequence of the discoveries begun in 1872 by Wislicenus, developed by van 't Hoff and Le Bel in 1874, and confirmed by an army of other workers down to the present day. We now not only suppose it probable that atoms are placed within a molecule in definite positions relatively to one another, but in a great many cases their order and arrangement in space can be positively traced.

Suppose all these great laws and principles never to have been discovered—science and its applications would not exist, and the world would have remained in about the same condition as it was in two hundred years ago. Railways, electric light and traction, telegraphs, dyes, explosives, antiseptics, anæsthetics and many other drugs, metals such as sodium, aluminium, magnesium, tantalum, and even modern steel would be unknown.

But these things are merely the results of the recognition, development, and application of the principles already indicated as fundamental, and the immediate corollaries from them. And so it seems that there are two fields for research which are equally necessary to civilisation and progress. In the one the worker watches the operations of nature and puts questions in the form of experiments solely with the desire to find out her ways; in the other attention is given only to those laws, facts, and phenomena which can be made serviceable to man. There is much more public anxiety in regard to the latter, and considering how entirely ignorant are most people about the principles of physical and natural science this is not greatly to be wondered at.

Some people are under the impression that there is an art of scientific discovery which can be communicated from one person to another. That is not my belief. I think the history of scientific discovery shows that each successful pioneer has invented methods for himself, or has at least known how to select from the tools ready to his hand. And with regard to personal qualifications, I do not think it possible to create that combination of mental powers which is called insight. Hence I have very grave doubts about the advisability of spending time and energy in trying to evoke and cultivate the capacity for research in all students in colleges and universities. If this were possible we ought to see greater results in those cases in which it has already been tried. The judicious teacher will, of course, be careful to avoid any appearance of indifference toward ardour and enthusiasm whenever they appear, and he should ever be on the look-out for indications of the kind of capacity which alone repays cultivation, and give it all the encouragement in his power. But the clamour which has of late been raised as to the supposed desirability of extending instruction in the principles and methods of research, down to the very beginners, indicates, to my mind, a lack of judgment on the part of some of the agitators. It seems to be forgotten that in every branch of experimental science, and especially of applied science, there is a great deal to learn, and it is necessary that at the end of his career as a student a young man should be able to *do* things practically and usefully. The theory of music and the laws of harmony are very desirable for the musician, but if he is to be a performer he must devote the greater part of his time to practice on his instrument, whether piano or violin. The case of the student of science is analogous, and if he does not devote a good deal of time to learning the technique of his business he will not be ready for research or anything else. At the present time too many students who can write at length on theoretical questions of a most recondite character, and who boast that they have been engaged in research under eminent teachers, are yet incapable of choosing a subject for themselves or of handling successfully a subject found for them by their teachers or someone else.

With the object of testing the influence exercised by methods of education in science on the development of the faculty of research, I have lately had the curiosity to compare the results indicated by the lists of Doctors of Science of the University of London. Up to 1886 this degree was awarded on the results of a very severe examination. From 1887 onwards it has been obtainable only on the production of a thesis supposed to embody the ideas and the work of the candidate on some subject selected by himself. The examiners are at liberty to impose an examination with the object of assuring themselves of the candidate's knowledge of his subject, but as a matter of practice the examination has been reduced to a mere formality. It was expected that this change of system would be followed by indications of much greater fertility in the fields of research. Owing to the completeness with which chemical literature is indexed, I have been able to make a comparison between the number and character of original papers published by the chemists in these two lists within the ten years following graduation in each case. I have not been able to make so strict a comparison among the physicists owing to the distribution of their work through so many media of publication, but I have been led by a careful survey to the same conclusions as in the case of the chemists. In both classes, the *Examinees* and the *Researchers*, if they may be so distinguished, there are cases in which the doctor, after taking his degree, has done no original work—or at any rate none that was fit for publication—and his name does not appear in the literature of his science. On the other hand both lists contain famous names. I will only mention in passing that the names of Larmor and Lodge appear among the examined. On the whole, I see no indications that the procedure by thesis has had any effect whatever on the character of the graduates. If anything, the list of examined is of somewhat higher quality than the list of graduates by dissertation, for there are nine out of fifty-four who have become Fellows of the Royal Society, while among the others there are only eight out of fifty-nine who can write themselves F.R.S.

In the latter list there may be one or two who may achieve this distinction hereafter, but there are no indications that in the long run the amount and quality of the contributions made to science by the graduates who are supposed to have been trained to research will surpass those of the men who had to face the ordeal of examination.

Does this not seem to justify my original contention that the researcher is born, not a product of educational manufacture, and that his disposition to research will survive all sorts of adverse conditions, including those which are by some people supposed to be inherent in examination?

I feel convinced that most of the great discoveries of the future will be made, as in the past, by the inspired amateur, working usually alone and often on apparently insignificant beginnings, and with results which may not at first receive any attention from the world.

It is, however, necessary in these days to provide for some form of cooperation in research, partly for the reason that the cost of some kinds of investigation is quite beyond the means of most private persons, and partly because of the unfortunate separation which still prevails, chiefly in this country, between science and industry.

First, then, science may justly look for assistance from the State. In England this is given in a grudging way. Parliament allots 4000*l.* to the whole range of the physical and natural sciences. The fund is administered by the Royal Society, and the biggest slices out of it are taken in the form of contributions to the expenses of expeditions. Then there is the National Physical Laboratory, with an expenditure of about 25,000*l.* a year, of which 7000*l.* comes from the Treasury. This seems to be all that comes directly from the national purse; but science is endowed to a certain extent by her friends. This assistance is represented by the equipment of certain schools and colleges by the Guilds of London, and by the small research funds of the Chemical Society and the British Association.

Something more systematic is, however, wanted, and I feel strongly that some of the rather large funds given in the form of scholarships to young students could be more advantageously used if applied to the maintenance of proved investigators to make them independent of the necessity to earn a living by teaching or other professional work. I recognise, however, the difficulties which would attend any such scheme. In the first place, discoveries cannot be made to order. An able, industrious, and conscientious man might work for many years without producing definite results, and a few cases of that kind would destroy or shake public confidence. It would also be necessary to provide incomes large enough to retain the services of the most able men available.

With regard to the application of science to industry, I think our manufacturers have made some progress during the last thirty years. But they still suffer from delusions. The mistake most commonly made arises out of a misapprehension of the methods, powers, and promises of science. It still seems to be too often supposed that a scientific man, called into hurried consultation, can at once overcome a difficulty in a manufacturing process or can devise an improvement which, if adopted, would represent many thousands of pounds profit to someone. If this were so scientific men would be better off than they usually are. What is wanted is a general recognition of the principle that improvements can be expected only as the result of the use of scientific methods, which are simply the methods of reason applied to the materials provided by experience.

What every manufacturer wants is to begin with a scientific education, if not for himself then for his sons or successors, so that those who are at the head of affairs may understand fully the problems before them and in what direction to look for help towards improvement. Failing this he will be dependent on the services of paid assistants, and those services cannot be expected to produce the desired results unless they are paid for on a liberal scale. In this country there has not hitherto been sufficient attraction to draw into the field of technology a due share of the best brains of the nation. The prospect of ultimately reaching a salary of two or three hundred a year at the utmost is not sufficient to induce a young man of first-rate ability to spend several years of his life and a thousand pounds or so of capital in scientific and technical studies; and so the supply of the highest class of scientific assistance is at present far from what it ought to be.

But suppose conditions to improve, a question arises as to the best way of turning such assistance to account.

A suggestion has lately been made that a new society should be formed, to be constituted of trade committees associated with experts in various divisions of science, to carry on experiments confidentially in the interests of the manufacturers who become members of the society. It seems to me that any suggestion is better than none if it results in the closer association of industry and science: but I think this particular proposal would not be found to work in practice. The requirements of different industries are too numerous and complicated to be met by an arrangement so simple, for each committee would find itself occupied with so many different problems that nothing would be accomplished, unless, indeed, the staff were very large. In my judgment each manufacturer must endeavour to work out his own salvation. Moreover, the experience of the German manufacturer, and to some extent also of the American, shows that it can be done effectively. The most famous example known to me is the case of the great Badische colour works at Ludwigshafen, on the Rhine. There is a factory which employs some 5000 men, and which pays, and has always paid, 25 to 30 per cent. or more on its ordinary capital. The great feature of its organisation is to be seen in the direct association of manufacture with research conducted by a staff of highly skilled scientific men.

In England arrangements so complete are unknown, and the number of highly qualified chemists and physicists employed in works is very small. I say nothing about engineers, with whom I am not so well acquainted, but the greater number of the chemists are merely testers doing routine work, and because such men, receiving the wages of a clerk, have not been able to advance the industries with which they are connected, their employers have in too many cases in the past come to the conclusion that science is of no use. In the meantime many things have happened. The neglect of organic chemistry in England forty years ago led to the complete removal of the coal-tar dye industry to Germany, where since that time has sprung up the equally important manufacture of synthetic drugs. The saccharin, the antipyrin, the artificial perfumes consumed in England are not made here, and it now looks as if the fixation of atmospheric nitrogen in the form of nitrate, so important from the agricultural and industrial points of view, was going to be taken possession of by Germany and America acting together, England being left out.

Such things have been said over and over again for the last thirty years or more, and I am not aware that such statements have been shown to be fundamentally mistaken, nor has there ever been any public excuse or explanation of the indifference so commonly displayed.

The link between science and industry must be established by the masters of industry themselves. I do not believe in the efficacy of much of the technical instruction which is talked about, and I fear that much money is being wasted in the attempt to imitate industrial operations in schools and colleges. What is wanted is the highest and most complete kind of instruction in pure science, following a good general education conducted on such lines that the fittest only are passed forward to the university or scientific school. Young people educated in this way form the material which should be utilised by the manufacturer. But he must not expect that a man so prepared is going to earn his salary the first year or two. He has got to learn his business, and must have facilities for doing this, or such talent as he has cannot be turned to account, and this can only be done by taking him into the works. This is a subject on which a great deal might and should be said, but such a discussion is not suited to the present occasion.

In conclusion, I may perhaps be allowed to give a few minutes to a glance at the future—not that I can pretend to descry very much.

We must remember that there is no finality in physical science. The farther we go the wider does the horizon before us become, but every discovery of a new fact or principle gives us a new instrument to help on to higher things. Hence we may reasonably suppose that, wonderful as the past has been, the future will be more wonderful still.

Here I will venture to draw a distinction between invention and discovery, and to invention there is probably no limit. It may be said to consist in making new combinations and permutations in the elements of knowledge already acquired. Among the inventions which have affected the condition of mankind, those which are concerned in locomotion stand first. It may truly be said that life is lengthened, not only by years, but by opportunities, and from this point of view quick travelling, provided by steam and electricity, is a great advantage. It would be unwise to utter any predictions as to what may hereafter be done with big ships and aëroplanes, only the old-fashioned type of nervous system—already shrinking from the increased noise and bustle of the town—shudders at the thought that neither distant valley nor mountain top, from the tropic to the pole, can now be expected to provide an asylum where peace secure from intrusion is to be found.

In Samuel Butler's "Erewhon," a remarkable book

published about forty years ago, a country was pictured in which moral delinquency was treated with sympathy and condolence, while bodily disease of all kinds was held to be a crime, and was punished by fine or imprisonment. I suppose it will take a good many generations to reach that condition of enlightenment, but the time cannot be far off when the propagation of infectious disease will in all civilised countries be abolished.

The habitability of the planet Mars has of late been a subject of much revived discussion. The possibility or probability of the existence of intelligent beings in other parts of the universe, long a subject of debate, is a question of profound interest, but whether communication with them from the earth can ever be established, who can tell?

But as to discovery in physical science, as already said, the horizon widens as we go on; but it seems not improbable that there is a limit set, though as yet very far off, by the capacity of the human intellect. Nature's ways used to be thought simple, but now we know that she is not only mysterious, but complex. However, there is every reason to expect that great strides are possible, even in the immediate future. The sort of problems which remain to be solved are represented by such questions as the following:—What is the cause and nature of gravitation and other sorts of attraction? What is the difference between positive and negative electricity, and what is the relation of electricity to matter? What is the nature of chemical affinity, and is it really electrical? What is the constitution of the elements, and is the transmutation of metals a dream or a physical possibility?

The penetration into final causes seems as we proceed to be further and further out of our reach. The problems of life and mind are, up to the present, inaccessible to man in his present state, and, notwithstanding the hopes and beliefs of some physiologists, it is safe to say that they will remain so for a long time to come, if not always.

And even in regard to common matter and the physical forces, all we know about them is derived from the perception of phenomena through the agency of our senses. Now the senses, sight, hearing, and the rest, have been evolved, not to provide the means of surveying nature, but for the protection and advantage of the body to which they belong. It is possible, therefore, that the human view of phenomena is only a partial and imperfect view; at any rate, the world which is open to the sense perception of a man must be very different from that which is perceived by many animals with their highly specialised senses, such as the scent of the dog, the sight of the carrier pigeon, and perhaps other senses for which we have no name.

"In its ultimate nature," said Herbert Spencer, "matter is as absolutely incomprehensible as Space and Time. Whatever supposition we frame leaves us nothing but a choice between opposite absurdities."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Vice-Chancellor has published to the Senate certain letters from the clerk to the Drapers' Company in which it is announced that the company is prepared to erect a physiological laboratory at Cambridge at a cost not exceeding 22,000*l.*, and to make a further grant of 1000*l.* for the equipment of it upon the following conditions:—(1) that the site be given by the University and approved by the company; (2) that the architect be appointed and the plans approved by the company; (3) that the University undertake adequately to maintain the laboratory when erected, and to provide the salaries of teachers and demonstrators. A Grace will be proposed at the next Congregation gratefully accepting the offer of the Worshipful Company of Drapers, and a syndicate will be appointed to discuss details with the company.

Mr. R. S. Goodchild has been reappointed assistant secretary to the Appointments Board for three years.

GLASGOW.—On Wednesday, October 26, the services of Prof. William Jack, who lately resigned the chair of mathematics in the University of Glasgow after a tenure of thirty years, were suitably recognised at an interesting and largely attended ceremony in the Bute Hall. Sir Henry Craik, M.P. for the University, presented to the Vice-Chancellor, Sir Donald MacAlister, K.C.B., a fine portrait of the professor, painted by Sir James Guthrie, president of the Royal Scottish Academy, which had been subscribed for as a gift to the Court by a large number of colleagues, students, and friends in all parts of the world. In addition, a sum of 300*l.* was provided for the foundation of a William Jack prize, to be awarded at intervals of three or four years to the author of the best dissertation on a mathematical subject submitted during the period in question for the degree of Doctor of Science in the University. A present of plate bearing a commemorative inscription was made at the same time to Prof. Jack. The latter, in an interesting speech of reminiscence, recalled the notable teachers and students with whom he had been associated during the half-century of his connection with Glasgow. His successor, Prof. Gibson, explained the value of the new prize as a stimulus to post-graduate study and research. The Vice-Chancellor, on behalf of the Senate and Court, acknowledged its debt to Prof. Jack, not only for what he had done, and done well, but for what he had been—the trusted friend and guide as well as the instructor of his students, the loyal comrade and peacemaker among his fellow-workers.

MR. S. BRIERLEY, formerly head of the Textile School, Stroud, has been appointed head of the textile department of the Huddersfield Technical College.

DR. J. A. EWING, C.B., F.R.S., Director of Naval Education to the Admiralty, will distribute the prizes at the Merchant Venturers' Technical College, Bristol, on Thursday, December 15.

MR. J. G. STEWART, of Edinburgh, has been appointed by the Essex Education Committee principal of the County Laboratory at Chelmsford. One of the chief duties of the office is to teach scientific farming to the agriculturists of Essex and Herts.

IT is announced in *Science* that Mr. J. D. Rockefeller has recently offered to give to Western Reserve University for further endowment of its medical department the sum of 50,000*l.*, provided 150,000*l.* additional is raised. Toward this 200,000*l.* fund Mr. H. M. Hanna, of Cleveland, has given 50,000*l.* The trustees of the University have indicated their intention to undertake to secure the 100,000*l.* needed to complete the fund. Yale University is to receive the residue of the estate of the late Mr. S. H. Lyman on the death of the testator's brother, with the exception of 5000*l.* The value of the bequest is not known, but the estate is said to be large.

IN NATURE of October 13 a letter appeared from Mr. E. G. Reiss, honorary secretary of the Apprenticeship and Skilled Employment Association, directing attention to the fact that a number of laboratory monitors in secondary schools, who, having reached the age of sixteen years, were no longer eligible for employment by the London County Council, wanted situations. Mr. Reiss writes to say that he has succeeded in placing in various suitable posts all the boys referred to, and points out that a number of girls who have been employed in a similar capacity also want suitable employment. As yet Mr. Reiss has been unable to discover posts for these girls, and would be glad of any suggestions as to openings for them. They are about seventeen years of age. The address of the association is 36 Denison House, 296 Vauxhall Bridge Road, London, S.W.

THE Yarrow Educational Fund of the Institution of Civil Engineers was established to afford assistance to young men who desire to become engineers, who have given proof of their capacity to profit by specialised education and training, but who lack sufficient means to obtain it. Grants varying between 50*l.* and 100*l.* per annum, for a period not exceeding three years, may be made in the discretion of the committee. Applicants for such grants must be of British birth, not more than twenty-one years of age, and must be prepared to qualify for attachment as students of the Institution of Civil Engineers. Several vacancies for scholarships under the fund will occur in March, 1911, and the council of the institution are prepared to receive and consider applications therefor.

Applications should be addressed to the secretary of the Institution of Civil Engineers, Great George Street, Westminster, S.W. Further particulars may be obtained on application to the secretary of the institution.

In the technical schools of this country the library is usually a comparatively unimportant factor in the intellectual work done by the institution in question. This is perhaps partly due to the insistent and ever-growing claims of the laboratories and workshops for apparatus, plant, &c. As a result of this and other causes, the higher work of many technical institutions is seriously hampered by the inadequate provision of scientific and technical literature, works of reference, and the journals of the learned societies. Not only is there a deficiency in the supply of books and journals open to the student, but in some cases the libraries themselves are small, badly lit, noisy, and crowded. This militates against fostering those habits of study which are essential to the progress of the student, especially as in some cases the technical student is unable to secure a quiet working place in his or her own home. The magnificent new library at the Battersea Polytechnic, recently presented by the munificence of Mr. Edwin Tate, and opened on October 21 by the Archbishop of Canterbury, is excellently adapted for study and reading by those attending classes at the polytechnic. The library is 70 feet long and 30 feet wide, and is erected at the south-western corner of the polytechnic, and can be approached both from the main corridor and the present reading-room. At the western end of the library is a wide bay containing a beautiful stained-glass window. The book-cases project at right angles to the wall, forming bays to seat readers, and the gallery runs round three sides of the library. The total book accommodation is 18,000 volumes. The whole of the fittings and panelling are of oak, the floor being of teak. As the building stands close to the road there are double casements, the inner ones being filled with ornamental lead glazing. As regards lighting, there is a separate window to each bay. Speaking generally, the library is planned on lines similar to those on which all modern university libraries are being developed, the books, for instance, being accessible at once to all students. The cataloguing is by card. Efforts are being made to obtain funds in order to increase very largely the technical and scientific portions of the library. It may be mentioned that the library is of considerable use, not only to students of the polytechnic, but also to certain local firms. Some little time ago a circular was sent from the polytechnic to the local chemical firms inviting them to utilise, if they wished, the works of reference and technical journals in the library.

At the meeting of the Education Committee of the London County Council on October 26 the question of the senior scholarships awarded by the council was under discussion. It was eventually decided to increase the number of these scholarships in 1912. Just as it was necessary to increase the number of intermediate scholarships in 1910 when the first batch of junior scholars attained the age of sixteen, so it will be necessary to increase the number of senior scholarships in 1912 when the same candidates reach the age of eighteen. The number of senior scholarships available for competition at present is 50; in 1912 it will be 100. The standard required for the award of these senior county scholarships is, however, not to be lowered in any way. It is estimated that the annual cost of awarding 100 of these scholarships will be 20,000*l*. In the award of senior county scholarships the council has regard, in the first instance, to the past achievements of the candidates and to the reports of the teachers under whom they have worked and of other responsible persons acquainted with the candidates, and such reports must have reference to the character and qualifications of the applicants as well as their scholastic attainments. The scholarships consist of a maintenance grant not exceeding 90*l*. a year. This amount is in each case determined after consideration of the requirements and the financial circumstances of the candidate. Senior county scholarships are, as a rule, tenable for a length of time necessary for a student to take an honours degree in the subject selected, provided that this period is not more than four years When the scholarship has been held for four years the council may, in a limited number of cases, continue the scholarship for a fifth year if satisfied that there are exceptional circumstances which render such further continuance desirable. At present the income of the parents or guardians of a scholarship holder must not exceed 400*l*. a year. A proposal to abolish this limit was referred back to the higher education sub-committee for further consideration.

SOCIETIES AND ACADEMIES.

LONDON.

Institution of Mining and Metallurgy, October 19.—Mr. Edgar Taylor, president, in the chair.—A. J. **Bensusan**: Notes on passagem mine and works.—R. H. **Kendall**: Treatment of refractory low-grade gold ores at the Ouro Preto Gold Mine, Brazil. These two papers, which were discussed conjointly, both deal with the same mines from slightly different points of view, so that one may be taken as the complement of the other. The ore treated is composed of quartz, tourmaline, arsenical and iron pyrites, with some bismuth, and the method of high concentration had to be adopted in view of the difficulties and losses encountered with amalgamation in the presence of arsenical pyrites and bismuth. The ore from the mine passes through grizzlies and rock-breakers to two series of Californian stamps, eighty head in all, and thence over blankets. The material remaining on the blankets is piped to *passadores* for daily concentration, and the concentrate passes through a second *passador* and thence to *bateas*, whence the gold dust is recovered, and the tailings return to the *passador*, and thence with the first *passador* tailings to the concentrates cyanide plant. The pulp from the mortar boxes passes over Frue vanners, whence the rich concentrates pass to the cyanide plant, and the tailings pass through spitzkasten and thence through the sands and slimes cyanide plants respectively. The papers describe the various processes and the plant in considerable detail, and give statistics as to costs, time of operations, and results.—J. Egerton **Wood**: A method of collecting gold from pannings. A short note dealing with a simple means of collecting and preserving gold values obtained in the field until such time as they can be be cupelled in the laboratory.

PARIS.

Academy of Sciences, October 24.—M. Émile Picard in the chair.—A. **Haller**: Two active alcohols and a third ketone contained in spirit from cocoanut oil. The raw material used in the investigation was a bye-product in the purification of cocoanut oil. Apart from acids separated by alkalies, possibly arising from saponification of fatty bodies, methyl-heptyl-ketone, methyl-nonyl-ketone, and methyl-undecyl-ketone were isolated, as well as methyl-heptyl-carbinol and methyl-nonyl-carbinol. The two alcohols were dextrorotatory, the optical inverse of the alcohols isolated from oil of rue.—M. **d'Arsonval**: The second International Congress for the Suppression of Adulteration.—Henri **Douvillé**: How species have varied. As the result of a comparative study of the Lamellibranchs, the author is of opinion that the evolutionary changes have not been continuous, but have occurred in a series of abrupt steps separated by periods of stability.—MM. **Landouzy** and L. **Loederich**: Experimental study of heredity in tuberculosis. The experiments were made on guinea-pigs, dogs, and rabbits, and evidence was obtained of direct placental infection. In the cases where there was no direct infection the mortality was very high from causes other than tuberculosis.—F. **Robin**: The variation of resistance of steels to crushing as a function of the temperature. Relations between the static and dynamic properties of the steels. Data are given for copper, nickel steel, manganese steel, and three steels containing 0·07, 0·384, and 1·8 per cent. of carbon at temperatures ranging between −185° and 1400° C.—Edouard **Salles**: The diffusion of gaseous ions. Experiments were carried out with air, carbon dioxide, nitrogen, and oxygen; measurements were carried out with air at two pressures, 758 mm. and 1028 mm., and with nitrogen at four, 760 mm., 1000 mm., 1120 mm., and 1302 mm.—J. **Duclaux**: Refrigerating mixtures. A lowering of temperature is produced when carbon bisulphide is mixed with acetone. A simple apparatus is described, utilising the regenerative

principle, by means of which a volume of 20 c.c. can be continuously maintained at a temperature 70° below that of the room, with an expenditure of 100 c.c. of carbon bisulphide and 70 c.c. of acetone per hour.—Jean **Villey**: The measurement of very small displacements by means of the electrometer. A condenser formed of two parallel plates and charged to a suitable potential is applied to measure extremely small displacements of one of the plates. Using an electrometer giving a motion of 150 cm. per volt on a scale 350 cm. distant, with a condenser formed of circular plates 6·5 cm. radius and 158 μ apart, a displacement of the spot of 150 cm. on the scale is obtained when the condenser plate, charged to 176 volts, is moved 0·001 mm., or a magnification of 1,500,000. The sensibility exceeds that of the interference methods.—J. **Carvallo**: The electrical purification of liquid sulphur dioxide and its electrical conductivity. Liquid sulphur dioxide, already fairly pure, is further purified by the prolonged passage of a current at a high potential. The limiting values obtained for the conductivity do not follow Ohm's law, but laws which recall those governing the conductivity of gases.—Paul **Nicolardot** and Georges **Chertier**: The nitrous esters of cellulose. In an attempt to find the cause of the differences in the percentage of nitric nitrogen in guncotton when determined by the Schlœsing and Crum methods respectively, the author was led to examine the action of the nitrogen peroxides on cotton in presence of glacial acetic acid. The nitro-products thus obtained appear to contain nitrites, and do not yield their true percentage of nitrogen by the Crum method.—MM. **Magnan** and **Perrilliat**: An acephalous human monster.—Mme. V. **Henri-Cernovodeanu**, MM. Victor **Henri**, and V. **Baroni**: The action of the ultra-violet rays upon the tubercle bacillus and upon tuberculin. After a short exposure to the ultra-violet rays the tubercle bacilli are attenuated; after a more prolonged exposure they are destroyed. Tuberculin, after a very long exposure (five hours), gives no reaction with tuberculous guinea-pigs.—A. **Fernbach** and A. **Lanzenberg**: The action of nitrates in alcoholic fermentation. Nitrates are not prejudicial to the fermentation.—E. **Roubaud**: The influence of the physiological reactions of Glossina in the salivary development, and the virulence of the pathogenic trypanosomes.—Paul **Marchal**: Contribution to the biological study of Chermes.—M. **Fabre-Domergue**: The storage of oysters in filtered water. After remaining for eight days in filtered water oysters do not diminish in weight, and do not appear to be depreciated in any way.—Carl **Störmer**: The situation of the zone of maximum frequency of the aurora borealis according to the corpuscular theory.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 3.

ROYAL SOCIETY, at 4.30.—The Origin of the Hydrochloric Acid in the Gastric Tubules: Miss M. P. Fitzgerald.—(1) Trypanosome Diseases of Domestic Animals in Uganda. II. *Trypanosoma Brucei.* (Plimmer and Bradford); (2) Trypanosome Diseases of Domestic Animals in Uganda. III. *Trypanosoma vivax* (Ziemann): Colonel Sir D. Bruce, C.B., F.R.S., and others.—Further Results of the Experimental Treatment of Trypanosomiasis; being a Progress Report to a Committee of the Royal Society: H. G. Plimmer, F.R.S., Capt. W. B. Fry, and Lieut. H. S. Ranken.—On the Peculiar Morphology of a Trypanosome from a case of Sleeping Sickness and the possibility of its being a new Species: Dr. J. W. Stephens and Dr. H. B. Fantham.—Note upon the Examination of the Tissues of the Central Nervous System, with Negative Results, of a case of Human Trypanosomiasis, which apparently had been cured for years by Atoxyl Injections: Dr. F. W. Mott, F.R.S.—On a remarkable Pharetronid Sponge from Christmas Island: R. Kirkpatrick.

LINNEAN SOCIETY, at 8.—Biscayan Plankton, Part XIII. The Siphonophora: H. B. Bigelow.—Plankton Fishing in Hebridean Seas: Prof. W. A. Herdman, F.R.S.

RÖNTGEN SOCIETY, at 8.15.—Presidential Address: Dr. G. H. Rodman.

MONDAY, NOVEMBER 7.

ARISTOTELIAN SOCIETY, at 8.—Self as Subject and Self as Person: S. Alexander.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—A Sixth Journey in Persia: Ancient Parthia, Nishapur, and Turshiz: Major Molesworth Sykes, C.M.G.

SOCIETY OF ENGINEERS, at 7.30.—Public Slaughter Houses: S. M. Dodington.

TUESDAY, NOVEMBER 8.

ILLUMINATING ENGINEERING SOCIETY, at 8.—Recent Advances in, and the Present Status of Gas Lighting: F. W. Goodenough.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The London County Council Holborn to Strand Improvement, and Tramway Subway: G. W. Humphreys.

WEDNESDAY, NOVEMBER 9.

GEOLOGICAL SOCIETY, at 8.—The Rhætic and Contiguous Deposits of West, Mid, and Part of East Somerset: L. Richardson.—Jurassic Plants from the Marske Quarry: Rev. G. J. Lane.

THURSDAY, NOVEMBER 10.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: The Tidal Observations of the British Antarctic Expedition, 1907: Sir George Darwin, K.C.B., F.R.S.—Conduction of Heat through Rarefied Gases: F. Soddy, F.R.S., and A. J. Berry.—The Chemical Physics involved in the Precipitation of Free Carbon from the Alloys of the Iron Carbon System: W. H. Hatfield.—On the Determination of the Tension of a recently-formed Water surface: N. Bohr.

MATHEMATICAL SOCIETY, at 5.30.—Annual General Meeting.—The Relation of Mathematics to Experimental Science (Presidential Address): Sir W. D. Niven.—Properties of Logarithmico-exponential Functions: G. H. Hardy.—The Double Six of Lines: G. T. Bennett.—On Semi-integrals and Oscillating Successions of Functions: Dr. W. H. Young.—On the Existence of a Differential Coefficient: Dr. W. H. Young and Mrs. Young.—The Analytical Extension of Riemann's Zeta-function: F. Tavani.—The Geometrical Representation of non-real Points in space of Two and Three Dimensions: T. W. Chaundy.—The Extension of Tauber's Theorem: J. E. Littlewood.—A Note on the Property of being a Differential Coefficient: Dr. W. H. Young.—The Stability of Rotating Shafts: F. B. Pidduck.—A Class of Orthogonal Surfaces: J. E. Campbell.—On Non-integral Orders of Summability of Series and Integrals: J. W. Chapman.—Optical Geometry of Motion: A. A. Robb.—Lineo-linear Transformations, specially in Two Variables: Dr. A. R. Forsyth.—On the Conditions that a Trigonometrical Series should have the Fourier Form: Dr. W. H. Young.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Presentation of Scholarships and Premiums.—Inaugural Address of the President: S. Z. de Ferranti.

FRIDAY, NOVEMBER 11.

ROYAL ASTRONOMICAL SOCIETY, at 5.

MALACOLOGICAL SOCIETY, at 8.—On the names used by Bolten and Da Costa for genera of Venerdiæ: A. J. Jukes-Browne, F.R.S.—On New Melaniidæ from Goram and Kei Islands, Malay Archipelago: H. B. Preston.—On the Anatomy of the British Species of the Genus Psammobia: H. H. Bloomer.—Note on *Triton tesselatus*: Major A. J. Peile.

PHYSICAL SOCIETY, at 8.—On the supposed Propagation of Equatorial Magnetic Disturbances with Velocities of the Order of 100 miles per second: Dr. Chree, F.R.S.—On Cusped Waves of Light and the Theory of the Rainbow: Prof. W. B. Morton.—Exhibition of a Brightness Photometer: J. S. Dow.

CONTENTS.

THURSDAY, NOVEMBER 10, 1910.

PHYSIOLOGY AS A SPECULATIVE SCIENCE.

Biological Physics, Physic, and Metaphysic. Studies and Essays. By Thomas Logan. Edited by Q. McLennan and P. H. Aitken. Vol i., Biological Physics. Pp. xxx+576. Vol. ii., Physic. Pp. viii+284. Vol iii., Metaphysics. Pp. vi+110. (London: H. K. Lewis, 1910.) Price, 3 vols., 24*s*. net.

IN a prefatory note we read that Dr. Thomas Logan was an Ayrshire man, who received his medical education at Glasgow and Aberdeen, and spent almost half a century on busy practice as a public health officer and general practitioner, first in Scotland, latterly in Yorkshire. He died three years ago, at the age of sixty-nine, leaving behind him the manuscript of the three volumes now published. It is stated that his editors were not permitted to make alterations or excisions of any of the text, which therefore appears in the form the author wished, and is illustrated by a number of cuts borrowed from standard works on anatomy and histology. The first volume is entitled "Biological Physics," the second "Physic," the third "Metaphysics."

Dr. Logan would appear to have been very early impressed with the truth of the aphorism, "Circulatio Circulationum omnia Circulatio," and the great bulk of his volumes is devoted to the repetition and amplification of this text. He possessed a great facility with the pen, and was never at a loss for a word or words to express his meaning. Hence his sentences run to 10, 15, or, in favourable instances, 25 lines or more in length. As a philosopher, he committed himself to unbridled speculation and unchastened teleology, employing the deductive method that has found so little favour since the end of the sixteenth century. Thus, for example, he showed (i., p. 165) that the axon of a nerve-cell must be—and therefore is—

"a compound of at least four tubes circulating fluids and substances of different consistence, and qualities, along its intra-spaces, each circulation differing from the other according to the consistence of its material and the freedom from obstacles to its onward progress, the two inner being necessarily slow, but the two outer necessarily relatively quick."

With every nerve-fibre acting as a four-fold tube, there can be no doubt that circulation might proceed merrily indeed; but anatomical or microscopical evidence either that these fibres are tubes, or that they do serve as circulatory channels. Dr. Logan offered none. He was, also, on purely *a priori* grounds, a firm believer in the importance and activity of the pituitary gland. After describing its position in the skull, he went on to say (i., p. 94):—

"Situated thus, it, the pituitary body, must become the receptacle of a mixture of materials, consisting of cerebro-spinal lymph, endothelial cell debris, neuroglial oozings, and whatever else obtains an entrance into it, which it must of anatomical necessity dispose of, and *this*, we claim, must be *its function*; and surely no mean function, yea, a function second to none in the whole category of glandular functions in its direct bearings on the great problem of life and health."

It may be noted in passing that he offered a solution for one at least of these great problems, by saying what life is (i., p. 445):—

"Life, therefore, is a tripartite, but indissolubly united, transcendental entity, beginning with the vitalisation of the elements of nutrition, culminating in their organic incorporation, and ending with their devitalisation and elimination."

Discussing the pituitary and pineal bodies, he did not agree that they are survivals of once important organs (i., p. 97):—

"*Survivals forsooth!* 'Tis nothing less than an insult to *nature*, and an impeachment of her working and administration of the law of 'evolution,' to manufacture and propagate this story of her prodigality in the use of most valuable cephalic, or brain, space as a museum for the storage of obsolete organisms, and her persistent exhibition of a juvenile affection for the display of some of the works of her 'prentice hand in this, the gallery of her latest, best, and finest productions! These structures, called pituitary and pineal glands respectively, are illustrations of the truth of this exclamation and contention, and, it seems to us, that their more exhaustive study will reveal many facts indicating that they are structures of the greatest functional importance in the regulation of the cerebro-spinal lymph circulation, a circulation of equal importance with the great blood-circulation, and a circulation, in fact, emanating from the blood-circulation, and the last of the *great series* of circulations involved in the *chain of vital processes* called by the names deglutition, digestion, absorption, circulation proper, nutrition, assimilation, secretion, and excretion."

Dr. Logan was no less successful in tracing out the path followed by these pituitary products; speaking of the tongue, he said (i., p. 545):—

"Here, then, we claim to see the theatre of one of the concluding acts of the great cerebro-excretory circulation and the final disposal of the residual pituitary material, which finds its way through the pituitary gland, and which in turn finds its way through the lateral sphenoidal foraminal openings into the tonsillar bodies, and thence into the amorphous and semi-adipose material matrix, in the inter-muscular spaces of the tongue, where it affords that semi-plastic and faintly-fluid material in the discharge of which the epithelial covering and papillary structures of that organ are constantly engaged."

One may doubt whether obscurantism could go further. Enough of Dr. Logan's writing has been quoted to exhibit the surge and flow of verbiage on which he launched his *a priori* theories, and floated his elaborate yet elusive and illusory deductions. Throughout his essays he was content with speculation and assertion, rarely did he come down to the level of simple fact and commonplace proof of his novel views. So little was he in agreement with the modern spirit or methods of scientific investigation that one cannot but see in him a writer fated to live some two or three centuries after his time. His volumes illustrate very clearly the strength and the weakness of the undisciplined scientific imagination, so-called, and show the limitations of the arm-chair man of science to perfection. They should be of no little interest to collectors of the literary curiosities of science.

A. J. J. B.

THE COMPLETE BOTANY-TEACHER.

The Teaching Botanist. A Manual of Information upon Botanical Instruction, including Outlines and Directions for a Synthetic General Course. By Prof. W. F. Ganong. Second edition, revised. Pp. xi+439. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 5*s.* net.

THE first edition of Prof. Ganong's book received a welcome on this side the Atlantic such as is accorded to few elementary botanical works produced in America, and it has proved of the greatest value to many engaged in the teaching of elementary botany, or in training as future teachers of the subject. The second edition, lately published, has been thoroughly revised, and, indeed, re-written almost throughout, besides being considerably enlarged, though the general plan, and, above all, the animating spirit of the book, not to mention the very moderate price, remain unchanged. To all intents and purposes this edition is a new work, and should be in the hands of all botanical teachers, both *in esse* and *in posse*, whether or not they already possess the first edition.

In part i., occupying, roughly, half of the book, the author deals in a practical, yet philosophic and stimulating, manner with the place of the sciences in education and of botany among the sciences, followed by a thoughtful and vigorous discussion of the pertinent question, "What botany is most worth?" and proceeds to the consideration of the training of the good botanical teacher, the methods of good botanical teaching, botanical drawings and descriptions, the equipment of laboratories, and the arrangement of collections. A valuable chapter follows on botanical books and their use, with a bibliography—by no means exclusively American—which, with a few deletions, would serve as the catalogue of an ideal library for any institution in which the subject is taught. One is inclined to wonder when there will be found an author—and publisher—courageous enough to publish a "black list" of undesirable books on botany and nature-study generally; but, after all, this would merely postpone for a time the oblivion into which bad books are bound to sink sooner or later.

As is well known, Prof. Ganong has shown himself, especially in his valuable "Plant Physiology," to be an acute critic of many erroneous facts and ideas, and of faulty methods of experimentation, which are only too common in botanical literature, not only in books of the baser sort, but even in standard and authoritative works. In the present work he ends part i. with a breezy and delightful chapter—only too short—on some common errors prejudicial to good botanical teaching, which will bring some discomfort to conscientious teachers, while pointing out to them the better way. Such teachers will, however, be to some extent consoled by the author's candid confession that he, too, has occasionally perpetuated, and even originated, ideas and phrases which are "unfortunate if not erroneous." This chapter is certainly deserving of most careful study by all teaching botanists.

In part ii. Prof. Ganong outlines a general course in elementary botany—not a mere skeleton or series of headings, but a thoroughly practical, fairly detailed, and altogether excellent syllabus of instructions for the carrying out of a very full year's work in the morphology and physiology of plants. It would be difficult to devise a better guide to the elements of botany for those who may go no farther with the subject, or a more suitable first-year course for those who intend to proceed to more advanced work in botany. This admirable and wisely designed course of instruction may be warmly commended, not only to teachers of botany, but to those who are responsible for the drafting of examination syllabuses in the subject in this country.

F. C.

CLIMATIC CONDITIONS AND ORGANIC EVOLUTION.

Die klimatischen Verhältnisse der geologischen Vorzeit vom Praecambrium an bis zur Jetztzeit und ihr Einfluss auf die Entwickelung der Haupttypen des Tier- und Pflanzenreiches. By Dr. Emil Carthaus. Pp. v+256. (Berlin: R. Friedländer und Sohn, 1910.) Price 8 marks.

THIS treatise commences with a consideration of the views of different authors upon the early evolution of the earth. Of the rocks in the earth's crust, Olivine rock (Dunite) is considered by the author to be the most primitive, its formation having taken place before the condensation of the water-vapour contained in the very earliest atmosphere. The gneisses, however, were formed after such condensation had occurred. The beginnings of organic life were present in the original atmosphere of water-vapour, but the author doubts the view of Arrhenius that the early spores could have reached the earth from other heavenly bodies. The period between the Upper Cambrian and Purbeckian was one of little rain, the existence of salt deposits in the early formations at various places widely separated from one another, and the complete absence of real freshwater calcareous deposits prior to the Jurassic being cited as evidence in support of that view. In this connection the interesting questions are propounded: Why have no remains older than the fauna of late Tertiary or diluvial times been found in the caves of Devonian, Carboniferous, Triassic, and Jurassic limestones? Why did cave formation thus probably begin first in Tertiary times?

The occurrence of forests of Rhizophora (Dicotyledons) in the sea of the Malay Archipelago is instanced as a reason against the assumption of the necessarily freshwater origin of the Ferns, Sigillaria, Lepidodendron, Equisetites, Conifers, and Cycads of the older geological formations. Great stress is laid upon the difference in the movements of the sea-water as affecting the forms of life at different times. The increase of these movements in later geological periods tended to destroy the brachiopods, the bilateral symmetry of the Tetracoralla gave way to the radial symmetry of the Hexacoralla, while the later Echinoidea, as compared with the earlier, underwent

changes in the number and arrangement of plates; the increasing complication of the ammonite sutures is explained on the same ground. It is pointed out that the multiplication in number of the sinupalliate Lamellibranchiata in Cretaceous time and their further acceleration in company with the Heterodont forms in the Tertiary period correspond with the incoming and continuance of freshwater conditions. In recent times certain Lamellibranch species in the Black Sea and Caspian Sea have wandered into brackish and fresh water, and as a result there is an increase in length of the siphon, a gaping of the shell, and the formation of a mantle-sinus.

The work has been written in the seclusion of an Indian hotel without the immediate advantages of close contact with the scientific world and its literature. This explains to a great extent the semi-popular nature of the book, and accounts, perhaps, for the omission of a bibliography other than rare and general references in the text. A division into chapters and the inclusion of a more extensive index would have been a decided improvement. Although controversial in many of its statements, the contribution has the undoubted merit of arousing interest and thought. The author appears to be a strong believer in the inheritance of acquired characteristics, and is not inclined to the assumption of an indwelling tendency towards perfection in forms of life; the followers of Cope, von Baer, Naegeli, and von Eimer would, therefore, find much material for debate. The statement that land or fresh-water animals and plants older than of Tertiary age are not found in the earth clefts of primary and secondary formations is certainly erroneous. For instance, the teeth of Microlestes found by Charles Moore and submitted to Owen in 1858 came from a Rhaetic breccia filling a fissure in the mountain Limestone, near Frome, Somersetshire.

IVOR THOMAS.

COMMERCIAL ORGANIC ANALYSIS.

Allen's Commercial Organic Analysis. Edited by Prof. H. Leffmann and W. A. Davis. Vol. II., Fixed Oils, Fats and Waxes, Soap, Glycerol, Cholesterols, &c. Fourth edition, entirely rewritten. Pp. x+520. (London: J. and A. Churchill, 1910.) Price 21s. net.

MOST analysts are aware that a fourth edition of Allen's well-known work is in course of preparation. Two of the eight volumes composing the edition have now appeared, and a notice of Vol. I. will be found in NATURE of June 16 last. Two more are announced for publication this year, and the remaining four are promised without undue delay. The plan of having both an American and an English editor has been adopted, and articles are contributed by writers from each side of the Atlantic. This seems a sensible arrangement, as with comparatively little modification the book is made to serve the needs of chemists in both countries.

The volume now under review is much extended and improved as compared with its predecessor of the last edition. Mr. C. A. Mitchell is responsible for the opening section describing the general properties of the fixed oils and fats, as well as the common processes of analysis, whilst the special characters of the individual products, and the particular methods of examining them, are discussed by Mr. L. Archbutt. Having regard to the scope of the book, both sections appear to be very well done. As much trustworthy information as could well be given in the space allotted will be found in these two sections, and no point of importance calling for adverse remark has been noticed by the present writer in looking through a number of representative pages. Perhaps the articles on arachis oil, olive oil, and the beeswax group may be singled out as good examples of compressed essentials. Sometimes, indeed, the compression is a trifle too marked. Many references, however, are given to original papers, so that fuller details can often be obtained.

Certain products, including butter, soap, and glycerol, are each given a special section. Messrs. Revis and Bolton have taken charge of the chapter on butter fat. They have studied their subject well, and, among other things, have grasped a fact which seems to have puzzled some experts on butter analysis—namely, that the addition of lard to butter may produce a distinct (apparent) increase of the "Polenske figure," which might be taken by the unwary as indicating the presence of cocoanut oil. One or two small errors have crept in; thus the Zeiss values in the first table on p. 290 are wrongly given as being taken at 40° C. instead of 45°, and there are two misprints in the second table on the same page. A favourable opinion, based upon the authors' own experiments, is expressed in reference to Lallemant's "barium saponification" method of examining butter fat. How far the commendation is deserved cannot be judged from the particulars given. For example, granted that the method detects cocoanut oil in butter, it may yet be that the detection could be made just as certainly and much more readily by older processes. The really difficult problem is the recognition of lard or beef-fat when present in butter, and it is in the promise of this that the chief importance of Lallemant's process lies. It will be interesting to see how it stands the test of experience when applied, on a sufficiently extended scale, to genuine butter having Reichert-Wollny values in the region of 23 and 24.

Of Prof. Leffmann's chapter on soaps and the other special contributions it must suffice to note that they contain all that an analyst will generally require to know on the subjects. They help to make the volume a distinct improvement upon the former editions.

C. S.

THE SEVEN LAMPS OF BIOLOGY.

Das System der Biologie in Forschung und Lehre. Eine historisch-kritische Studie. By Dr. Phil. S. Tschulok, Zürich. Pp. x+409. (Jena: Gustav Fischer, 1910.) Price 9 marks.

THE author discusses at great length some of the attempts that have been made to define the scope of biology, and to indicate the logical sub-divisions of the science. Starting with early workers like Ray,

he works on to A. P. De Candolle and Schleiden (of whose importance he is very appreciative), and thence to Haeckel and Spencer, Karl Pearson, and Burckhardt. This laborious historical survey, which must have cost the author much time and trouble, is interesting to those who care for such questions, but it seems to us to be robbed of some of its value by being overloaded and by a lack of perspective. Dr. Tschulok quotes classifications of the different departments of biology from a large number of text-books, some of which are rather humdrum performances, while others are by men who left a deep mark on the science, but had neither any particular interest in mapping out its subdivisions, nor any special aptitude for so doing.

To illustrate, a man like Burckhardt was a good zoologist—too early lost to science—but he was also a philosopher. He went the length of thinking about the classification of the sciences, about the relation of biology to other disciplines, about methodology, and so on, his writings sometimes reminding us of those of Prof. Patrick Geddes in this country. Naturally, therefore, we are glad to have from Dr. Tschulok an exposition of Burckhardt's views, and we are especially grateful for the unearthing of an essay on the history of biological "Systematiks," well-buried "an einem ziemlich versteckten Orte." But what we regret is the space that is given to what are really incompetent classifications. The author wearies us with citations from manuals of botany, which start with commonplace mappings out of the science, sometimes beginning with a weird word like "Glossology," and ending up with "Fossil Botany." The last is a careless usage, which in an interesting irony sometimes justifies itself. Our regret that the author has been at such pains to expose the nakedness of the land is heightened when we find that he has missed most of the few really illuminating British contributions to the subject of his book. We may refer, for instance, to well-known encyclopædia articles by Prof. Patrick Geddes and Sir E. Ray Lankester.

The author divides biology into Biotaxis and Biophysik. The first has to do with the establishment of conceptual relations, the second with the establishment of real relations—causal and teleological. Classification, for instance, is "biotactic"; physiological analysis is "biophysical." He contrasts his dual division with others, *e.g.*, with morphology and physiology (which is a "scholasticism," he says), or with biostatics and biodynamics, which expresses a different idea. But does Dr. Tschulok mean more than this, that we have in biology, as elsewhere, to discover the orderliness of sequences and to sum this up in conceptual formulæ?

The author's chief contribution is a scheme of the subdivisions of biology. His idea is that there are seven kinds of inquiry which are individually indispensable and collectively exhaustive. These are: taxonomy, morphology, physiology, œcology, chorology, chronology, and genetics. This appears to us to illustrate most of the vices of classification, such as overlapping, cross-division, and inequality of values. It appears to us, for instance, that taxonomy and morphology are inseparably bound together; that œcology, as Semper said, is part of physiology; that chorology is not an independent division of the science; and so on. It must be noted, however, that Dr. Tschulok defends his seven-fold classification with enthusiasm and learning. J. A. T.

A MONOGRAPH OF THE PETRELS.

A Monograph of the Petrels (Order Tubinares). By F. Du Cane Godman, F.R.S. With hand-coloured plates by J. G. Keulemans. Part iv., pp. 233–296; part v., pp. 297–381+lv. (London: Witherby and Co.) Price 15*l.* 15*s.*, bound in full morocco.

THE fourth and fifth parts of the "Monograph of the Petrels," completing this beautiful and valuable work, have been received, and the whole work can now be had, bound in full morocco, price fifteen guineas. It contains 436 pages printed on rag paper, and over one hundred hand-coloured plates by Keulemans, our best ornithological artist. In every respect this beautiful volume has been produced in the best possible style. Nor is the letterpress any less excellent. The work was projected, if not actually begun, by the late O. Salvin, who wrote the "Tubinares" for the British Museum catalogue of birds, and the author has endeavoured to carry out the work on the lines laid down by Salvin, taking the catalogue as his guide. The final part contains a masterly introduction to the order Tubinares, a systematic list of species, a classification and key to the genera and species, and an essay by Mr. Pycraft on the systematic position of the petrels.

Petrels apparently belong to an ancient race of birds, as their remains have been found in a fossil state in various parts of the world, mostly in superficial deposits, one species, however, being known from the Red Crag of Norfolk. In external appearance the families of petrels differ in an extraordinary manner, and the species vary in size from the tiny storm petrel to the wandering albatross. Notwithstanding their wide differences, petrels may at once be distinguished from all other birds by their prominent tubular nostrils and by their bills, which consist of several horny pieces separated by deep grooves. They are dispersed throughout the oceans of the world, penetrating to the ice barrier at both Poles, though they are more numerous in the southern than in the northern hemispheres. They are oceanic wanderers, and, unless storm-driven, seldom, if ever, come to land except for the purpose of breeding.

The two parts now before us comprise the rest of the genus Œstrelata, and the genera Pagodroma (the snowy or ice petrel) Bulweria, Macronectes (the "stinker or Nelly" of the sailors), Fulmarus, Daption (the well-known "Cape Pigeon"), Halobæna, and Prion, completing the family Puffinidæ; the family Pelecanoididæ comprising one curious genus; and the family Diomedeidæ (the albatrosses), comprising the genera Diomedea, Thalassogeron, and Phœbetria. Certainly the most curious and perhaps the most interesting of all these are the strange little

diving petrels peculiar to the southern seas, and absurdly resembling the little auk of the northern seas both in appearance and habit—diving, fishing, and flying—although widely differing in structure. Darwin wrote of one of them:—

"No one seeing the bird for the first time, thus diving like a grebe, and flying in a straight line, by the rapid movements of its short wings, like an auk, would believe that it was a member of the family of petrels, the greater number of which are eminently pelagic in their habits, do not dive, and whose flight is usually most graceful and continuous."

Since the completion of Salvin's catalogue the present monograph has derived much benefit from the considerable additions to the national collection made through the several expeditions sent to the Antarctic regions, among which may be mentioned the voyages of the *Discovery*, the *Southern Cross*, the *Scotia*; and from the cruises of the *Valhalla*; as well as from the expedition sent to the Hawaiian Islands by the Hon. Walter Rothschild; these together have considerably increased our knowledge of the distribution of the petrels. A full index brings this important volume to a close.

OUR BOOK SHELF.

Eugenics, the Science of Human Improvement by Better Breeding. By C. B. Davenport. Pp. 35. (New York: Holt and Co., 1910.) Price 50 cents net.

THIS useful little book consists of two parts. The first is an account of the principles which determine whether a given marriage will produce fit or unfit offspring, the second contains suggestions for future eugenic research. In the somewhat limited class of characters and diseases for which definite Mendelian laws of inheritance have already been made out, it is possible to predict with an approach to certainty the proportion of the children which will or will not be affected. Thus the malformation of the fingers known as brachydactyly is a Mendelian dominant. "An abnormal person married to a normal will beget 100 per cent., or 50 per cent. abnormal, according to circumstances, and such a marriage is unfit; but two parents who, though derived from brachydactyl strains," are themselves normal, "will have only normal children . . . such a union is entirely fit."

Deaf-mutism may be due to any one of a variety of defects, but in different individuals of the same family the chance is large that it is due to the same defect. Such defects are often recessives, and may appear in the offspring of normal parents of deaf-mute stocks. Intermarriage between two such parents, especially of cousins, is "unfit." Again, too, imbecile parents, whether related or not, produce only imbecile offspring, a fact which should impress those responsible for the long delay in embodying in legislation the recommendations of the Royal Commission on the Care and Control of the Feeble-Minded.

In concluding his suggestions for future inquiry, Mr. Davenport rightly points out the contrast between the difficulty of raising funds for such scientific inquiries, and the ease with which money is obtained for charitable and humanitarian action which often proves to have been ill-judged.

"One cannot fail to wonder that, where tens of millions have been given to bolster up the weak and alleviate the suffering of the sick, no important means have been provided to enable us to learn how the stream of weak and susceptible protoplasm may be checked." W. C. D. W.

The Book of the Dry Fly. By G. A. B. Dewar. New edition. Pp. xxvii+277. (London: A. and C. Black, 1910.) Price 7s. 6d. net.

THE second edition of Mr. Dewar's "Book of the Dry Fly" follows the first after an interval of thirteen years. It is to be regretted that this second edition is, in reality, little more than a reprint of the first; the art of dry-fly fishing has been developed, and knowledge of the natural history of the trout and of the aquatic creatures upon which it feeds has advanced during these years, and it is a little deceptive to find that references to "last year" in a book with 1910 on the title-page refer to 1896. The deception may even be turned to confusion by the addition of a footnote modifying or contradicting the statements made in the text.

However much we may regret that the book has not undergone a more complete revision, we may still be glad to find that a second edition has been published. Mr. Dewar is a student of nature, as well as a fisherman, and he writes with obvious enthusiasm and interest of various chalk and limestone streams and their surroundings. He deals well with the elements of dry-fly fishing, and appears to touch on most points likely to interest a student of that art.

There are some matters in which we find Mr. Dewar hard to follow, such as his discussion of the modern higher education of trout, but as a rule his explanations are lucid and his opinions clearly expressed. The grayling is, perhaps, treated with rather scant courtesy in the text, although the footnotes show signs of a change of view. A singular misuse of the term "dropper" in chapter ii. is obviously the result of an oversight, and this should be corrected in any future edition.

An attractive feature of the present edition of Mr. Dewar's book is the series of excellent reproductions of water-colour sketches of typical chalk and limestone streams; these should assist the fisherman who does not know the waters of Hampshire or other southern and Midland counties to appreciate the conditions which have brought dry-fly fishing into being far more easily than any mere description in words.

Last, but not least, there is a good index.

Die Entwicklung des menschlichen Geistes. By Max Verworn. Pp. iv+52. (Jena: Gustav Fischer, 1910.) Price 1 mark.

THIS is a lecture by the well-known professor of physiology in the University of Bonn, and is a kind of popular survey of human development. After dealing with the fact that "the development history of the individual form is a short recapitulation of its race development" (Fritz Müller) and with the elaboration of this by Haeckel, Dr. Verworn goes on to emphasise the importance of child-study with relation to pedagogics. A eulogy of Charles Darwin follows, and a curious and interesting table of supposed psychological development from the Eolithic to the present time.

The British Empire in Pictures. A Geographical Reading Book. By H. Clive Barnard. Pp. 64 (London: A. and C. Black, 1910.) Price 1s. 6d.

THE thirty-two excellent illustrations in colour which form the distinguishing characteristic of this book will serve excellently to predispose young pupils in favour of the study of geography. As a supplement to the more serious work of the class-room, the book should prove useful, and it should not be difficult to get children to read the book as a leisure-hour undertaking.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Origin of Dun Horses.

IN discussing the colours and stripes of horses in "Animals and Plants under Domestication," Mr. Darwin says:—"I have endeavoured, but with poor success, to discover whether duns, which are so much more oftener striped than other coloured horses, are ever produced from the crossing of two horses, neither of which are duns. . . . One case, however, has fallen under my own observation of a foal from a black mare by a bay horse, which when fully grown was a dark yellow-dun and had a narrow but a plain spinal stripe."[1]

In a recent number (October 15) of the *Veterinary Record* Mr. J. B. Robertson gives the following instances of reversion to dun from the last eleven and first four volumes of the General Stud Book:—

(1) Bay-dun filly (1907), by Ash (chestnut), out of Unexpected (bay).

(2) Dun filly, Sarah Curran (1892), by Robert Emmett (bay or brown), out of Cellulites (black).

(3) Dun colt (1897), by Sir Frederick (bay), out of Lobelia (bay or brown).

(4) Light dun filly (1886), by Lord Gough (bay), out of Danseuse (brown).

(5) Dun or chestnut filly, Sancta (1884), by Exminster (bay), out of Halloween (chestnut).

(6) Dun filly (1763), by Young Cade (bay), out of Miss Thigh (grey).

(7) Dun colt (1730), by King George II.'s one-eyed grey Arabian, out of Young Kitty Burdett (bay).

(8) Dun filly (1829), by Lottery (brown), out of Octavia (bay).

Mr. Robertson also mentions (1) that a half-bred yellow-dun filly was obtained out of a liver-chestnut Welsh cob by a bay thoroughbred with a dorsal band—this filly "during early foalhood was profusely striped on the face, neck, and quarters"; and (2) that of 45 duns given in the tables included in his paper, 39 cannot be traced to an original dun ancestor. They sprang from the union of Silverlocks (chestnut) and the Godolphin Arabian (brown), "and hence afford incontrovertible evidence that a gametic line of duns—which in this case extended to four generations—may spring from parents neither of which are dun."

The University, Edinburgh. J. C. EWART.

Markings of Mars.

I HAVE recently returned by way of Tasmania from a series of visits to the chief observatories in the United States, which included a month's stay at the Lowell Observatory during the past opposition of Mars. This visit was made with the express object of testing by my own observation the reality of the data on which Dr. Lowell has based his speculations.

I find on my return that so much scepticism has been raised by the observations and arguments of M. Antoniadi and others that a record of my own experience may be of some value.

When I first looked at Mars at Flagstaff (September 27, 1909) I saw with great difficulty three streaks, presumably canals. The seeing was bad, and the general faintness of the planet's markings at that time is admitted by all. I continued to observe Mars on every possible night (which was nearly every night) until October 25, and as my eye became accustomed to the work I saw more and more. The canals were seen repeatedly better—this with the 24-inch refractor generally stopped down to about 18 inches. I found that with more than 20 inches the air was nearly always too unsteady, and with less than 15 inches too much separating power was lost. The canals were seen best with a power of 390 diameters.

Clearer they became each night until, on October 25, the seeing being the best I ever experienced, the canals came out with amazing clearness and steadiness, sharp and clean, like telegraph wires against the sky, the oases also being exquisitely defined. Whereas on previous nights the canals could be held only by short glimpses of perhaps half a second at a time, they were now steadily visible for three or four seconds together, when a short flicker would sweep over them; during the lucid intervals the limb also of the planet was perfectly steady, as I have never seen it before or since. Of the objective existence of these markings in the image at the focus of the telescope there could be no manner of doubt, and Lowell's representations of them are nearer the actual appearance than any I have seen, though even in his drawings the lines seem hardly fine enough. The effect produced on my mind by this remarkable definition, which lasted for upwards of one and a half hours (from about 8.30 until after 10 p.m.), was staggering and ineffaceable. Soon after ten the definition went to pieces.

It may be relevant to mention that a few evenings previously I had obtained a fair and convincing view of the canals with the 40-inch reflector (full aperture and a power of about 700), when they had appeared hazy and broader, but the image had been very unsteady, and only obtained in very short flashes; but nothing that I had hitherto seen had prepared me for the astonishing steadiness and *fineness* of the details visible on this superb night.

There is in my mind no sort of doubt that the revelation of this night was due both to the perfection of the instrument (which its maker long ago pronounced to be the best that the firm of Alvan Clark ever turned out) and the atmospheric conditions which are found at Flagstaff. With respect to these I would mention, as pointing to the freedom from water vapour, that I have seen the thermometer fall from more than 70° F. at 3 p.m. to below the freezing point at 3 a.m. without a trace of hoar-frost, and the general clearness of the air was such that I could see Uranus with the naked eye within 5° of the horizon, and could nearly every night count nine stars in the Pleiades and separate ϵ and 5 Lyræ.

The telescope also afforded on other nights ample evidence of the extraordinary clearness of the air. On many occasions both satellites of Mars, when not very near the limb, could be seen, without screening the planet, with 18 inches of aperture; and on one occasion with this aperture I picked up one of them unawares while looking for canals with *a yellow screen*. (N.B.—The importance of colour screens in rendering the canals visible does not seem to be sufficiently appreciated.)

In the face of all this positive evidence, and in the absence of any evidence that the observing conditions at Meudon, just outside Paris, ever approach these best conditions at Flagstaff, I find it impossible myself to attach any serious weight to the ingenious and plausible contentions of M. Antoniadi, which seem to have been much too hastily accepted in this country.

As to the deductions which Dr. Lowell has drawn from his observations I have nothing to say except that the startlingly artificial and geometrical appearance of the markings did *force* itself upon me.

JAMES H. WORTHINGTON.

Wycombe Court, High Wycombe, October 31.

November Meteors.

THE moon is full about the time when the Leonids become due in the present year, but that is no reason why these meteors should elude observation, for the Sickle has furnished some notable displays of shooting stars. With the moon in opposition in mid-November, as, for instance, in 1799 and 1867, though the coming apparition cannot be expected to vie as regards brilliancy with either of these historic events, yet in its way it may not prove unimportant nor be allowed to pass unobserved. Besides the Leonid epoch, there are also some other meteoric events that occur in November, of which the following particulars have been computed by the writer:—

Epoch, November 11, 9h. (G.M.T.), approximately second order of magnitude. Principal maximum,

[1] "Animals and Plants under Domestication," vol. i., p. 62. (1872.)

November 12, 5h. 45m.; secondary maximum, November 12, 9h.

Leonid epoch, November 17, 21h., twenty-eighth order of magnitude. Principal maximum, November 16, 13h. 45m.; secondary maxima, November 16, 13h. 20m. and 15h. 30m.

Epoch, November 19, 9h., eighth order of magnitude. Principal maximum, November 20, 15h. 15m.; secondary maxima, November 20, 6h. 30m. and 16h. 30m.

Epoch, November 19, 9h. 30m., fifth order of magnitude. Principal maximum, November 20, 14h. 30m.; secondary maxima, November 19, 20h. 30m., and November 21, 0h. 30m.

Epoch, November 23, 22h., approximately second order of magnitude. Principal maximum, November 21, 20h. 30m.; secondary maximum, November 22, 1h.

Epoch, November 28, 6h., approximately second order of magnitude. Principal maximum, November 30, 14h. 30m.; secondary maxima, November 30, 2h. 30m. and 11h. 30m.

It may be seen from the foregoing that there are four periods during the last three weeks of November that will probably be characterised by an unusual degree of meteoric activity, viz. November 12, 16, 20–21, and 30. The circumstance that the moon will be eclipsed in the night of November 16 may favour and stimulate Leonid observations, but the former phenomenon will perhaps have nearly ended before the latter may put in an appearance.

November 7. JOHN R. HENRY.

Early Burial Customs in Egypt.

IT is suggested in Prof. Elliot Smith's letter (October 27, p. 529) that the burial customs in other countries influenced our observation of the burials in Egypt. On the contrary, the occasional practice of dismemberment in Egypt was a surprise to myself and to others; it is only gradually that the evidence for the wide distribution of such customs elsewhere has been brought forward as a parallel.

In place of all workers in Egypt finding "precisely the same state of affairs," many entire differences of custom are found in other material facts besides dismemberment, as thirty years' experience has proved.

The first principle for the archæologist to realise in Egypt is the great diversity of thought and custom which prevailed. With four totally incompatible beliefs about the future life, shown by diverse funeral customs throughout the history, it is quite natural that diversity should occur in the treatment of the body in the earlier ages. When the long-promised publication of Dr. Reisner on prehistoric Egypt is accessible, we shall be in a position to define some more localities where certain customs ruled. Discussion of these local variations before the fresh facts are published is premature.

W. M. FLINDERS PETRIE.

STRIPPED of all irrelevant considerations, the question at issue resolves itself into this, "Is there any real evidence to prove, or even to suggest, that the ancient Egyptians ever mutilated the bodies of their dead?"

In reply, I maintain that there is no evidence whatsoever capable of being twisted into the semblance of support to Prof. Flinders Petrie's contention.

Of all the multitudes of so-called "dissected burials" recorded by him, there is only one (see "Deshasheh," 1898) which carries conviction to those familiar with Egyptian conditions as a genuine case of secondary burial. Prof. Flinders Petrie says he has found two more cases this year. That may well be so. We found more than a score of such cases in Nubia.

But they are not evidence of deliberate mutilation of the body. They are all of them instances of some unintentional damage to the corpse—either by unskilled embalmers or by accident.

In reference to Prof. Flinders Petrie's closing remarks, I may state that by the time this letter is printed there will be published in Cairo Dr. Reisner's report (vol. i.) on the Archæological Survey of Nubia, containing his observations on prehistoric Egypt and Nubia.

G. ELLIOT SMITH.

Simulium and Pellagra.

THE interesting discovery by Dr. Louis Sambon that pellagra is due to a protozoal parasite conveyed by flies of the genus Simulium (NATURE, October 27) is, we may presume, merely the prelude to an energetic campaign of extermination directed against the insect.

It is well that medical men and sanitary officials should realise at the outset of such a campaign that the destruction of Simulium flies in any given area is an infinitely harder task than the destruction of mosquitoes. The larvæ of Simulium live in rapid streams, attached to submerged rocks and stones, and it is difficult to see how these streams can be drained dry if they are numerous in any particular district. Even if it were practicable to cover the surface of these streams with a film of oil, such a procedure would have no effect on the Simulium larvæ, for, unlike mosquito larvæ, the little creatures derive the oxygen necessary for their existence from the water bathing the gills situated at the anterior end of their bodies. In other words, the Simulium larva cannot be suffocated as can the mosquito larva.

Finally, it may be noted that the species of Simulium are very small flies, consequently to exclude them from houses wire gauze or muslin screens of extremely fine mesh must be employed. Such screens are bound to interfere seriously with the circulation of air in a house, and in a warm climate the discomfort entailed will be almost intolerable. R. SHELFORD.

Hope Department, Oxford University Museum.

The Cocos-Keeling Atoll.

DURING a very short visit to these islands some years ago I was taken across the lagoon in a light canoe, and when wading to land, about a quarter of a mile distant, over the rough surface of fresh coral branches, I suddenly crashed downwards for about 2 feet into a mass of rotten coral which spread over an irregular area some 20 or 30 yards across. I did not investigate this further, as a shark's fin appeared above the water off shore, but Mr. Ross informed me that a good deal of the coral in the lagoon had been "killed" at various times by sulphurous exhalations from below, and had become black and rotten in consequence. Mr. Ross (the owner of the island group) supposed that the wide and deep well-like holes and broad irregular patches of varying depth in the lagoon were due to this cause, which he compared to the sulphurous steam constantly roaring from the crater of the Gedeh and other mountains in Java.

If this comparison be correct, as it doubtless is, the Cocos ring is around the submerged summit of a volcanic cone which has not quite lost its solfataric activity. I have never seen it suggested that such poisonous exhalations coming into the still water confined within the atoll ring might account for the slower growth of the coral, and the deepening of the lagoon by the degradation of the coral branches where the polyps had been suddenly poisoned. It is, however, possible that some such influence may cooperate to prevent the coral flourishing as rapidly as it does outside the ring in the boisterous wash of the fresher waves that are constantly stirred by the trades.

I have not yet read Mr. Wood-Jones's book, but it was the decided opinion of Mr. Ross, founded upon boat navigation, that the lagoon was shallowing, because, as he thought, the submerged summit was slowly rising. If this be so something more than slower growth is necessary to account for the continued existence of the lagoon, since, however slow the growth, it must ultimately in a rising area bring the summit up at least to water-level; but if there is this kind of active degradation, neither slow upheaval nor slower growth could prevail against such rapid destruction, and a comparatively deep atoll with irregular bottom contours would result.

Waterstock, Oxon, October 31. E. C. SPICER.

IT would be ungenerous, after the frank admissions of inaccuracy on the part of the reviewer (NATURE, October 27), to criticise the substance of his review in any more detail; but it is necessary to make some reply to his assertions concerning the development of atolls.

From the general trend of his first article (NATURE, October 6) I gathered that the reviewer was an advocate of the "solution" theory of Sir John Murray, and by carefully reading his second contribution (October 27) I have not entirely dispelled this impression. Yet he says, "I do not regard the lagoon in an atoll, which was formed, as Darwin suggested, by subsidence, as covering a reef at all."

This would seem to suggest a belief in Darwin's theory, and, if it is the case that the reviewer upholds this theory (as well as the opposed one of "solution"), it may be well to point out that I too would not regard the lagoon of an atoll, formed by subsidence, as covering a reef. I should not have imagined it probable that anyone would so regard a lagoon were it formed in such a manner. The essential difference between such a view and the one that I have attempted to uphold is that I do not regard the lagoon as being formed by subsidence at all; but I do look on the lagoon as being a "slightly submerged reef" having a raised rim upon which islets are developed. Does the reviewer genuinely regard the lagoon as being formed by subsidence? If he does, why does he also plead the opposed theory of solution, and appeal to the *elevated* islands of Fiji? If he does not, why does he urge the statement as an argument against my views?

I am glad to see that he is prepared to admit that the various well-known phases of development of atoll-shaped reefs are "indirect evidence" of the truth of what I have maintained; but the Funafuti bore, he thinks, does not support it. The reviewer states that he does not think "the borings in the lagoon at Funafuti suggest a reef such as surrounds a lagoon." I should not have expected them to have suggested a reef such as *surrounds* a lagoon, for that reef is a consolidated and specialised "breccia platform." What might be expected is that such a bore would show the characters of a submerged reef—the open coral bank—*plus* the lagoon accumulations added since the completion of the atoll.

When such a successful bore is driven we may look for such appearances; but it is surely within the knowledge of the reviewer that the only bore at Funafuti which met with any success was *not situated in the lagoon.* The lagoon bore ("bore L") penetrated only 144 feet, and then failed; the only successful bore (on the results of which alone any safe argument may be based) was situated on the seaward reef, far removed from the lagoon. The successful bore ("main bore"), which reached a depth of 1114 feet, was driven on the extreme windward edge of a large atoll reef. In such a situation one would confidently expect the bore to penetrate the talus slope of the outwardly growing reef, and, from the description of the core obtained, it would appear that this expectation was realised. The Funafuti "main bore" tells little of the development of atolls save that they grow to windward on their own talus slopes—a fact hardly requiring a laborious boring for its acceptance.

The "L bore" can support no particular theory by reason of its very incompleteness; but such evidence as it does afford in no way contradicts, but rather goes to support, the supposition that it penetrated the lagoon débris of a submerged reef.

Whether the reviewer regards the Funafuti boring as evidence supporting Darwin's theory of subsidence or Sir John Murray's theory of solution I cannot quite determine; but he next defends the solution theory in the case of the Fijian Islands. He says that these islands have reefs "which superficially appear to be of the ordinary coral-reef type. Such reefs cannot have existed when the islands were first elevated, and it seems to me that Agassiz's photographs show that high islands do crumble to pieces within the calm of encircling barrier reefs." I own that I fail to follow this argument, for, granting that the reef is new since the island was elevated, what proof—or what probability—is there that the coast erosion was not present before the development of the reef, when the same condition is seen quite apart from reefs, or any other coral structures, all over the world?

The problem of the formation of coral structures (fringing reefs, barrier reefs, open reefs, atoll-shaped reefs, and atolls) is not, I think, to be solved by appeals to a multitude of opposed theories, and no critic's position is likely to gain strength by a series of fallacious arguments based alternately on the theory of subsidence, the theory of solution, and the results of the Funafuti bore.

F. WOOD-JONES.

St. Thomas's Hospital Medical School.

As a reviewer I would point out that I do not desire to uphold any theory, but merely to show what is good and what is bad in the book which I am reviewing, what facts are new, how far these and other facts support any theories, &c. An essay on the duties of a reviewer might be a suitable suggestion to the Editor of NATURE, but obviously I am not the author to present such an article.

In the first paragraph of Mr. Wood-Jones's letter of October 27 I am practically accused of being an "anonymous destructive critic" of, I suppose, the constructions erected by the facts brought together by Mr. Wood-Jones, some of them new and some old. I regard some of the bricks of his building as faulty, and I scarcely think there are enough bricks with which to complete the building. I intended to indicate in my review that I considered that science had gaine by the attempt to build, and I desired indirectly to indicate some of the bricks which I thought future workers should attempt to collect. I do not believe any researcher on the coral-reef problem will consider my review as in any way unfair if he regards (*as I did*) Mr. Wood-Jones's book as a *contribution to science.*

I shall after this letter not continue this correspondence, not caring for Mr. Wood-Jones's style of writing. I would, however, make myself clear on two points. Mr. Wood-Jones admits that he assumes the lagoon of an atoll to be a slightly submerged reef. I point out that the nature of the material underlying the lagoons of atolls is doubtful. I appeal to the lagoon boring at Funafuti as giving the most valuable facts we have as to its nature. Do these facts, the best known geographical facts, support the theory of a *slightly submerged reef*, such as is supposed to exist at Cocos-Keeling? Down to 27 fathoms the first Funafuti lagoon boring passed through lagoon débris, and from that depth to 41 fathoms there occurred some firmly compacted masses of coral rock. In the second boring, which was carried to nearly 36 fathoms, a similar section was obtained. I do not consider that these two borings are sufficient to justify Mr. Wood-Jones's assumption, and I did not consider that the evidence given as to Cocos-Keeling lagoon justifies it. I quite fail to remember any description of the material under the Cocos-Keeling lagoon such as would suggest the open coral bank which is mentioned in Mr. Wood-Jones's letter, while its shallowness made it a peculiarly favourable place for investigation.

The fringing reefs round the high limestone islands in Fiji I certainly am inclined to regard as platforms left at low tide-level when those islands were washed away. In this sense they are new. They formed part of the bases of the islands when they were first elevated. Possibly the edges of these platforms have extended seaward since the land was removed by solution, and, still more important, by the erosion of the numerous small particles carried in the swirling waters. I consider these views are amply supported by published evidence. High limestone islands are also being washed away within barrier reefs, and I think it is a fair inference from the evidence that many of these barrier reefs were once similar shelves cut out from the land, or, to put it another way, left behind when the land was removed.

THE REVIEWER.

Note on Winter Whitening in Mammals.

I HAVE just seen a letter in NATURE of March 24 by Miss I. B. J. Sollas, in which, commenting on Mr. Mudge's observations, it is suggested that the yellow body produced artificially by Mr. Mudge in the fur of the albino rat is a substance similar to the yellow pigment of the stoat's winter coat, and therefore probably represents a stage in the reduction of the pigment to the condition in which it exists in the white hairs.

I had previously read Mr. Mudge's observations with great interest, and had suggested to him that they would throw light on the hitherto unexplained yellow tints in

the fur of the winter-whitened stoat, as well as in the permanently white polar bear. I think Mr. Mudge's observations are a distinct help to us in getting at the meaning of these white coats. I should like to see what Miss Sollas can do with the hair of the variable hare, as in the whitened specimens of this animal I have never seen any trace of the yellow tints found in the stoat.

Mr. Mudge's note that the white areas of a piebald mouse can be turned pink by immersion in 5 per cent. nitric acid in 78 per cent. spirit, but only in summer or a warm temperature, is also of great interest. Does it not suggest a reason why pink colour in feathers is mostly found in summer plumages and in warm climates? And is not his production of brown in the hairs of white rats exposed to damp warm weather comparable with the well-known saturated tints so prevalent in animals living naturally in damp but warm countries?

While writing on winter whitening it may be well to direct attention to another point, which has always been difficult to explain on physiological grounds, namely, the fact that the black ear tips of the hare and the black tail tip of the stoat are not subject to winter whitening. This, however, would be explicable if, whereas the general body coat of both these animals is cast twice a year, the black hairs on the ears and tail are renewed only once a year. If they are renewed only once they must remain (apart from fading) of the same colour throughout the year. That such a single moult is possible, and even probable, in these two instances is shown by the fact that in the squirrel there are two moults of the general body coat, but only one of the ear tufts and tail hairs. Similarly in the Equidæ (according to Ewart), there are two moults of the general coat but one only of the mane and tail.

G. E. H. BARRETT-HAMILTON.

Kilmanock House, Campile, Co. Wexford, Ireland, November 3.

Helium and Geological Time.

I MUST apologise for an error in my letter published in NATURE of November 3. The sixteenth line and onwards should read "... for we have no knowledge of chemical affinity between helium and solid substances; while, in respect of solubility, it would probably be inferior to the other gases."

R. J. STRUTT.

Imperial College of Science, South Kensington.

THE SUBANTARCTIC ISLANDS OF NEW ZEALAND.[1]

THE naturalists of New Zealand have always shown themselves eager to take advantage of any opportunity for extending our knowledge of the fauna and flora of their country. Such opportunities are presented from time to time by the periodical official visits of the Government steamer to the outlying islands. In November, 1907, the s.s. *Hinemoa* deposited a large party of New Zealand men of science on Auckland and Campbell Islands, calling for them again on her return trip more than a week later. The expedition was undertaken at the instance of the Philosophical Institute of Canterbury, primarily for the purpose of extending the magnetic survey of New Zealand to the outlying southern islands, but the volumes before us consist chiefly of zoological and botanical observations, though there are also articles on geophysics and geology.

The work has been issued under the editorship of Dr. Charles Chilton, and the publication has been rendered possible by a substantial subsidy from the New Zealand Government. It comes at an opportune moment, and acquires a special interest in relation to the exploration of the Antarctic continent now in progress.

FIG. 1.—Cliffs of Columnar Basalt, Enderby Island. From "The Subantarctic Islands of New Zealand."

The time at the disposal of the expedition was, of course, all too short for a complete biological survey, and the collections were evidently, at any rate in many cases, very fragmentary, but many very interesting results were obtained. The zoologists were undoubtedly right in devoting most of their energies to the terrestrial fauna, which is much more likely to be modified or even exterminated by human agency than the marine fauna, but we cannot help wishing

[1] The Subantarctic Islands of New Zealand. Reports on the Geo-Physics, Geology, Zoology, and Botany of the Islands lying to the South of New Zealand. Based mainly on Observations and Collections made during an Expedition in the Government Steamer *Hinemoa* (Capt. J. Bellons) in November, 1907. Edited by Prof. Charles Chilton. Vol. i., pp. xxxv+388; vol. ii., pp. 389–848. (Wellington, N.Z.: Philosophical Institute of Canterbury. London: Dulau and Co., Ltd., 1909.) 2 vols. Price 42s. net.

that the latter had received a little more attention. No fewer than 168 species and varieties of Foraminifera were discovered by Mr. Chapman in the dredgings sent to him, and if other groups are equally well represented in these seas there must be a rich harvest waiting to be reaped. Incidentally we may note the surprising and very satisfactory fact that of these 168 species and varieties of Foraminifera, from a practically unknown region, only four species and two varieties had to be described as new! Such a record gives one hope that some day our systematic knowledge of the marine fauna will be approximately complete. In the report on the sponges, on the other hand, Prof. Kirk mentions only two species, and of holothurians there were only three.

A large proportion of the collections, both botanical and zoological, has been worked up and reported on

FIG. 2.—Young Sea-lion (*Arctocephalus hookeri*), Carnley Harbour, Auckland Islands. From "The Subantarctic Islands of New Zealand."

by local naturalists, Prof. Benham, Prof. Chilton, Prof. H. B. Kirk, Mr. Edgar Waite, Mr. Henry Suter, Mr. E. V. Hudson, Mr. T. Brown, Mr. T. F. Cheeseman, Dr. L. Cockayne, Mr. R. M. Laing, and Mr. Donald Petrie, many of whom also took part in the expedition. Other collections were sent to specialists in other countries and reported upon by them.

Amongst the more interesting forms obtained, we may note two new species of land nemertines, from Auckland and Enderby Islands, a remarkable addition to this extremely limited group. These are described by Mr. A. D. Darbishire, who contributes some useful notes on the taxonomic value of certain anatomical characters. In addition to the purely systematic reports, we have others of more general interest. Thus Dr. Cockayne contributes a long essay on the ecological botany of the islands, with a number of beautiful photographic illustrations, and Dr. Chilton gives us an account of the history of the scientific investigation of the islands, and a very useful summary of the biological results of the expedition, especially from the biogeographical point of view.

The results in general appear to support the current view that the existing islands of New Zealand are mere fragments of a very much larger land area, which at one time extended southwards beyond Campbell Island, eastwards beyond Chatham Island and Antipodes Island, and north-westwards towards New Guinea. Thus the fauna and flora are essentially Novæ-Zealandian in aspect, but with a large Antarctic element which may perhaps be accounted for by a former northward extension of the Antarctic continent. The existence of an Antarctic continent has, of course, long been used in explanation of certain striking resemblances between the fauna and flora of New Zealand and those of South America, but, as Dr. Chilton points out, we must also suppose that at some former time the climate of Antarctica was sufficiently mild to allow of the existence of a far more abundant animal and vegetable population than we find there to-day. Such a supposition is justified by the geological observations of recent Antarctic expeditions. Fossil leaves were found near the winter quarters of the *Discovery*, and coal still further south by Shackleton, while the Swedish Antarctic expedition met with abundant fossil plants in rocks of Tertiary age on Seymour Island, indicating a temperate or subtemperate climate.

In conclusion, we must congratulate the New Zealand naturalists on the performance of a fine piece of work, and at the same time express our regret that they still have to labour under numerous disadvantages. Of these the want of adequate scientific libraries appears to be one of the most serious. The New Zealand Institute, with its various local branches, has for many years past played a most useful part in promoting scientific research in the dominion, and it appears to us that the Government might do well to assist in some scheme whereby the defect referred to might be remedied, and the necessary scientific literature provided, not only for Wellington, which is the headquarters of the New Zealand Institute, but also for those large provincial towns where the principal branches of the institute are situated.

ARTHUR DENDY.

BIRD MIGRATION.[1]

OF all the many problems of animated nature awaiting solution, few, if any, have of late received more attention than—perhaps the most mysterious of all—the migration of birds.

Mr. Eagle Clarke and the other painstaking observers working with him have during the last few years learnt and taught us much, but only enough to show that still, as Prof. Newton wrote some twenty years ago, "our ignorance is immense."

What is the propelling power which at the appointed seasons sets the great hosts in motion? It seems now at least probable that almost every bird is in some degree migratory, and that even the robins and thrushes that come to the windows for crumbs in winter are more often than not other birds than those which nested in the garden in the spring.

When and how in the long-past eternity were the great aërial highways from zone to zone first marked out, to last apparently for all time? Our boasted

[1] "Ornithological Notes from a South London Suburb, 1874–1909. A Summary of Thirty-five Years' Observations, with some Facts and Fancies concerning Migration." By F. D. Power. Pp. 60+chart. (London: Henry J. Glaisher, 55–57 Wigmore Street, W.) Price 3s. 6d. net.

Roman roads, Aitken streets and Watling streets are, compared to these, things of yesterday.

How is the knowledge of the chart passed on, without fault or break, from generation to generation? If old birds led the way the matter would be less incomprehensible. But, writes Herr Gätke, as "the *incontestable result*" of fifty years' watch in Heligoland:—

"under normal conditions, the autumn migration is initiated by the young birds from about six or eight weeks after leaving the nest.

"The parents of these young individuals," he adds, "do not follow until one or two months later"!

How and under what physical conditions are the journeys made?

Mr. Pycraft is a writer to whom ornithologists already owe much, and from whom they confidently look for more. His views will always carry weight, but they may change. Just now he thinks it "hardly necessary to attempt to bring rebutting evidence" to confute Herr Gätke's closely-reasoned argument that migration flights must be made at speeds which,

"Through the mists and vapours,
Amid these earthly damps,"

may well seem incredible; but, with atmospheric resistance removed, need seem no longer so.

The veteran ornithologist's dream of "the existence of a special respiratory mechanism, enabling birds to remain in strata of the atmosphere beyond the reach of all other organised beings," may yet prove true. There are things more improbable. Then we shall think nothing of flights at a speed of "a hundred and eighty miles an hour."

"Airy navies grappling in the central blue"

not many months ago seemed impossibilities. Now they seem uncomfortable probabilities.

These are a few only of the questions which have yet to be answered before we can hope to understand what the migration of birds means. The answers are not likely to be given in the lifetime of our generation, if ever. It is only by the patient collation of trustworthy observations, spread over a long series of years, that any general conclusions can be hoped for. We may sow, but others must reap.

A modest and unpretending little volume, lately published, "Ornithological Notes from a South London Suburb, 1874–1909," by Mr. F. D. Power, is a useful contribution to the general stock of knowledge of a fascinating subject. The first chapters of the book, well worth publication though they are, will appeal rather to local than to general readers.

It is interesting to know what birds are to be looked for in one's own neighbourhood, and where and when they have been seen there. But there is not much to be said of thrushes and tits in Surrey or Middlesex which is not to be noted as well in other counties.

There is the usual sad tale to tell—and it is very well told—of wild life crowded out by growing human populations.

The lake in Dulwich Park, for instance, was once, Mr. Power writes, a favourite resting-place for passing ducks. He has seen "on and about this comparatively small sheet of water seven species not observed elsewhere in the district. In one day in October, 1898, there were five scaups and four shovellers on the lake, and the tufted duck nested on the island for three or four years." The common sandpiper was a regular visitor, and the kingfisher not uncommon. Boats have been placed on the water, and "the saddened bird-lover has now little chance of even an early morning note of extra interest."

On Mitcham Common, once a favourite nesting-place of many small birds, golf balls have taken the place of eggs.

It is in the "Migration Notes," and more especially in a broadsheet table printed at the end, that the chief interest of the volume for ornithologists living beyond the "South London Suburb" will be found, and a very real interest it is.

Mr. Power has, during a long succession of autumn migrations, kept careful records of the forces and direction of the wind and of the size and direction of the flights passing within sight of his garden. In a simple and admirably clear chart, the results of his observations are shown for every day, without a single gap, for the month of October for twenty-five years.

The rather surprising conclusions to which his observations have led him would seem to find at least *prima facie* justification in the facts tabulated. He sums up as follows:—

"It used to be supposed, and by many the idea is still held, that birds come and go with wind favouring them. . . . My observations during these many years have convinced me that migrants travel best and by choice *against* the wind. . . . My experience is [he is speaking of the autumnal migration] that the only *visible* and *sustained* migration *in numbers* is invariably in a N.W., W., or S.W. direction *almost directly against the wind*, even when such approaches a stiff breeze, the birds in their progress meeting the wind on the right or left breast."

The italics are Mr. Power's.

The photograph of "the garden from which the migration notes were taken" does not, certainly, suggest exceptionally favourable opportunities.

His little book, like Alphonse Kerr's delightful "Voyage autour de mon jardin," shows how much is to be seen by "the observing eye" without going far from home.

T. DIGBY PIGOTT.

NEW DISCOVERIES AT KNOSSOS.

ON September 16 a letter appeared in the *Times* from Dr. Arthur Evans, describing the results of his excavations this year at Knossos. All archæologists will congratulate themselves on the fact that Dr. Evans has passed out of the path of politics, which he had essayed to tread, back into the more peaceful (?) ways of archæology. For there were many more things that we wanted to know about Knossos, and one of them has been made clear by the work of this season. The great domed pit, the *tholos*, as it seemed to be, over which part of the southern quarter of the palace was built, has been excavated to the bottom, not without danger to the workmen. And it turns out to be a great *tholos*-like reservoir, with a spiral staircase round the inside of it, which breaks off, as in other similar cases, at what must have been the average water-level. The springs that supplied this reservoir are now dry, and no doubt were so before the place was entirely filled up. This was done, as we know from the character of the potsherds found in it, in the first "Middle Minoan" age.

"In other words the reservoir itself belonged to the Early Minoan Age, and was filled in at the time of the construction of the first Palace of which we have any existing remains—the object of the work being to obtain a secure foundation for the South Porch and adjoining parts of the outer wall. The filling materials themselves were probably supplied by the levelling away at this time of the summit of the 'Tell' of Knossos in order to gain the area for the Central Court of the Palace." There was also a smaller reservoir on another part of the mound, "and from the magnitude of the work we may well conclude that some earlier predecessor of the Great Palace already existed on the site that it has since occupied."

This is an important conclusion. If we are to judge by the reservoir, the early Minoan palace was probably a great architectural work. The "Early Minoan III." architects were perhaps almost as capable as their contemporaries, the Egyptian pyramid-builders of the fifth and sixth dynasties.

In the small "palace" on the hillside west of Knossos further discoveries have been made, including a paved way with the rut-marks of ancient Minoan chariots. In this part of the site more recent remains, of classical and Roman date, constantly are found above the Minoan level; whereas in the main palace, "whether owing to a superstitious awe or to other causes, the hilltop . . . was never invaded by later habitations." A fine metope of a Doric temple, contemporary with the Parthenon sculptures, was found over the western palace.

Mr. Doll has proceeded with the work of conserving the palace buildings, and has run the great staircase another flight higher. Also the nature and composition of the frescoes have been studied by Mr. Noel Heaton.

In the tomb-field of Isopata further important discoveries have been made, owing to the *flair* of Gregori, Dr. Evans's Cypriote foreman,

"the most expert tomb-hunter of the Levant. . . . The wild, long-rooted fennel, which seeks out by preference the spots above ancient cuttings, served him, as often before, as a guide, and the result was the discovery of six chamber-tombs, some of which for their size and the interest attaching to their contents and arrangement surpass any hitherto known of this class."

The date of the tombs is the second late Minoan period, about 1450 B.C., contemporary with the eighteenth dynasty of Egypt. The most remarkable point about these tombs is the information as to Minoan religion which they give us. In one tomb, where "the religious interest culminated," was found an arrangement wholly new, which "rather recalled the domestic Etruscan ideas of the after-life than anything yet known of the Minoan age." The tomb was made to resemble a house of the living, with stone-cut benches, as if for family gatherings. And at the head of the sepulchral cist were found the remains of a double-axe shrine, with an offering-vessel, in the shape of a bull's head, lying close by. These tomb-chambers seem not to have been kept open regularly, but were opened for solemn service on the anniversary of the death probably. They were rifled of their more valuable contents by robbers of the early Iron age (geometrical period), who left behind them traces by which we can identify their date.

"It will be seen that the 'Tomb of the Double Axes' has produced more definite evidence regarding the sepulchral cult and religious ideas as to the after-world than any grave yet opened in Crete or prehistoric Greece."

Dr. Evans's comparison of the interior of the tomb with that of an Etruscan grave is very apposite and suggestive. This Etruscan impression has already been given by the great painted sarcophagus found by the Italians at Agia Triada, and it is most interesting to see how a relationship between the Etruscan, Minoan, and Anatolian (Hittite) cultures in matters of religious cult is gradually becoming clearer to us.

H. R. HALL.

NOTES.

THE following is a list of those who have been recommended by the president and council of the Royal Society for election into the council for the year 1911 at the anniversary meeting on November 30:—*President*, Sir Archibald Geikie, K.C.B.; *treasurer*, Mr. Alfred Bray Kempe; *secretaries*, Sir Joseph Larmor and Dr. John Rose Bradford; *foreign secretary*, Sir William Crookes; *other members of the council*, Mr. L. Fletcher, Dr. W. H. Gaskell, Sir David Gill, K.C.B., Dr. E. H. Griffiths, Prof. W. M. Hicks, Prof. F. S. Kipping, Major P. A. MacMahon, Mr. H. R. A. Mallock, Dr. C. J. Martin, the Duke of Northumberland, K.G., Prof. W. J. Pope, Prof. J. H. Poynting, Prof. E. Rutherford, Mr. A. E. Shipley, Mr. M. R. Oldfield Thomas, and Mr. Harold W. T. Wager.

THE Royal Society's medals have this year been adjudicated by the president and council as follows:—The Copley medal to Sir Francis Galton, F.R.S., for his researches on heredity; the Rumford medal to Prof. Heinrich Rubens, for his researches on radiation, especially of long wave-length; a Royal medal to Prof. Frederick O. Bower, F.R.S., for his treatise on the origin of a land flora; a Royal medal to Prof. John Joly, F.R.S., for his researches in physics and geology; the Davy medal to Prof. Theodore W. Richards, for his researches on the determination of atomic weights; the Darwin medal to Mr. Roland Trimen, F.R.S., for his South African bionomic researches, in large part undertaken as the outcome of correspondence with Charles Darwin; the Sylvester medal to Dr. Henry F. Baker, F.R.S., for his researches in the theory of Abelian functions and for his edition of Sylvester's "Collected Works"; the Hughes medal to Prof. John A. Fleming, F.R.S., for his researches in electricity and electrical measurements. The King has been graciously pleased to approve of the award of the Royal medals.

AT the meeting of the Royal Society of Edinburgh held on November 7, the following honorary fellows were elected:—*British:* Prof. J. G. Frazer, Sir Joseph Larmor, F.R.S., Dr. Alfred Russel Wallace, O.M., F.R.S. *Foreign:* Prof. Hugo de Vries, Amsterdam; Mr. F. A. Forel, Morges; Prof. Karl F. von Goebel, Munich; Prof. J. C. Kepteyn, Gröningen; Prof. Elie Metchnikoff, Paris; Prof. A. A. Michelson, F.R.S., Chicago; Prof. W. Ostwald, Leipzig; Prof. F. W. Putnam, Harvard University; and Prof. A. F. L. Weismann, Freiburg (Baden).

IT is reported from Stockholm that the Academy of Sciences has decided to award this year's Nobel prize for physics to Prof. J. D. van der Waals, of Amsterdam, for his work on gases and liquids.

WE regret to see the announcement of the death of Mr. Theodore Cooke, for many years principal of the Poona College of Science, at seventy-four years of age.

A REUTER telegram from Wellington, New Zealand, states that Mr. Priestly, who accompanied Sir Ernest Shackleton, as geologist, on his Antarctic expedition, is going out with Captain Scott in the place of Mr. Thompson, who is ill.

THE date of the annual exhibition held by the Physical Society of London, which was fixed some time ago for December 13, has been altered to Tuesday, December 20. The exhibition will be open in the afternoon as well as in the evening.

THE annual Huxley memorial lecture of the Royal Anthropological Institute will be delivered on Tuesday, November 22, at the theatre of the Civil Service Commission, Burlington Gardens, W., by Prof. W. Boyd Dawkins, F.R.S., whose subject will be "The Arrival of Man in Britain in the Pleistocene Age."

MRS. TYNDALL has presented to the Royal Institution two Nicol's prisms, constructed for the lectures on light given by Dr. Tyndall in America in 1872, and used by him sub-

sequently in his researches and lectures; also two pieces of rocksalt, the remains of a large block given to Dr. Tyndall by the King of Württemberg in 1867.

THE eighty-fifth Christmas course of juvenile lectures, founded at the Royal Institution in 1826 by Michael Faraday, will be delivered this year by Prof. Silvanus P. Thompson, F.R.S., his subject being "Sound, Musical and Non-musical: a Course of Experimental Acoustics."

THE General Purposes Committee of the Birmingham City Council has recommended to the council that an invitation be given to the British Association to meet in that city in 1913. The council will cooperate with the University and other public institutions in making the necessary arrangements.

THE death is announced of Dr. Carl S. N. Hallberg, professor of pharmacy in the Chicago College of Pharmacy in connection with the University of Illinois. He was born in Sweden in 1856, and emigrated to America when a lad. He organised in 1885, and subsequently directed, the National Institute of Pharmacy. Since 1906 he had edited the Bulletin of the American Pharmaceutical Association.

THE Simon Newcomb library, which has been presented to the New York City College by Mr. John Claflin, has just been classified and catalogued. It is a collection of 4000 volumes and 6000 pamphlets, and includes many mathematical and astronomical publications of unusual interest. Among them may be mentioned an early edition of Euclid's Elements, a Pacioli of 1494, the 1515 edition of the Almagest of Ptolemy, and the first book ever published on sun-spots.

MR. G. M. MEYER sends us an extract from the Madrid weekly periodical *Nuevo Mundo* of October 6 in which a Spanish case of eugenic policy is described. It appears that an illustrious Salamancan, Don Federico Gómez-Arias, founded an annual prize of 1000 pesetas, which is awarded every year to a young woman of Salamanca from fifteen to twenty-three years of age, of good physical constitution, attractive, and well conducted, who must have received at least an elementary education and be on the point of being married to a man of similar physical and moral condition and of suitable age.

BY the generosity of Sir Julius Wernher, who recently placed a sum of 10,000*l.* at the disposal of the committee for the purpose, a much needed extension of the department of metallurgy of the National Physical Laboratory has now been commenced. The department has been accommodated in scattered rooms in Bushy House, which, in consequence of the increase and importance of the work, have become quite inadequate. Plans have been prepared in consultation with Dr. Rosenhain, the superintendent of the department, and the contract has been let to Messrs. Dick, Kerr and Co., who have already made good progress with the foundations.

THE programme for the 157th session of the Royal Society of Arts is being issued to the members. There will be five ordinary meetings before Christmas, at the first of which the usual address will be given by the chairman of the council, Sir John Cameron Lamb. The papers announced for the other four meetings are by Sir Henry H. Cunynghame, K.C.B., "Detecting Fire-damp"; Mr. C. P. Ogilvie, "Argentina"; Dr. Vaughan Cornish, "The Panama Canal"; and Mr. Reginald Smith, "Roman London." There will also be a meeting of the Colonial Section, at which Mr. A. Montgomery will read a paper on "Mining in Western Australia," and one of the Indian Section to be occupied by a paper by Mr. R. F. Chisholm, on "The Taj Mahal." On the four Mondays before Christmas Mr. C. R. Darling is to give a course of Cantor lectures on "Industrial Pyrometry." There is also a very full list of papers and lectures for the part of the session after Christmas.

A QUARTERLY periodical entitled the *Botanical Journal* is issued as the official organ of the Royal Botanic Society of London. The first number contains an account of the history of the society since 1839, the date of the Royal Charter, in which are set forth the objects which have been served in that period. In recent years progress has been impeded by a lack of sufficient financial support, and consequent increase of debt, but the latest report shows that in some measure, at least, this condition is being remedied. The number of Fellows now is 1834, as compared with 1570 last year. The debenture debt is 14,714*l.*, as compared with 24,248*l.*, and the current liabilities 572*l.* instead of 3050*l.* Prof. A. J. Ewart, of Melbourne University, has an article on "The Flora of Victoria," and other subjects treated upon include "Our Native Lawns," "The Melbourne Botanic Gardens," "Fruit-growing in Queensland," and "Art in the Garden." There are notes upon botanical questions of interest and recently issued books. Two plates in colour from paintings by Miss Bertha Maguire prettily illustrate chrysanthemums, but their value is purely decorative, for they shed no light on the evolution of the flower, as would appear to be the case from the title. Mr. Butler's colour photographs are welcome, because they illustrate interesting plants in the society's collection. The number is not entirely free from the blemishes common to first issues: especially is this the case in the awkwardness of some of the titles to the subject-matter. The journal is issued by Messrs. Page and Pratt, and the price is one shilling.

THE Bulletin of the Johns Hopkins Hospital for October (xxi., No. 235) contains an appreciation of the life and work of Lord Lister, by Mr. Charles Judd, with bibliography; an historical inquiry on the decussation of the pyramids (nerve tracts in the brain), by Dr. Thomas; and an historical sketch of the practice of blood-letting, by Dr. Joseph Smith. Dr. Thomas ascribes the first definite observation of the crossing in the medulla of the great motor tracts passing from the brain to the spinal cord to Francois Pourfour du Petit (1664–1741). The practice of blood-letting or "bleeding" is at least two thousand years old, and is mentioned by the earliest medical writers.

UNDER the provisions of the Indian Museum Act of 1910, the ethnological and art collections have been separated from those of economic products, and in his last report of the museum as originally constituted, the curator, Mr. I. H. Burkill, has given a useful account of its past history and present condition. The museum was first started by the Asiatic Society in 1814, the first donor being the Countess of Loudoun. The collections have passed through many vicissitudes, due to the absence of suitable accommodation. Under the present scheme of reorganisation they have at last been placed upon a satisfactory footing. The ethnological gallery now contains about 11,000 exhibits, but it still lacks a proper descriptive catalogue, which can be prepared only by a competent ethnologist. The progress of the art series has been stimulated by the patronage of Lord Curzon, who provided an annual State grant of about 400*l.* for the purchase of specimens. Most of the older economical exhibits have perished, but these are being gradually replaced. It is satisfactory to learn that these important

collections are now being arranged in suitable galleries, and it only remains for the Government of India to provide a series of descriptive catalogues prepared by competent experts, which will render the exhibits available for study by students of art, anthropology, and the exonomic sciences in Europe.

PART 8 of vol. v. of the Annals of the South African Museum contains five articles on the entomology of the country. Among these, Mr. E. Meyrick continues his description of new Microlepidoptera, while Messrs. A. Raffray and L. B. Billecoq treat, in separate communications, of two groups of Coleoptera.

To the *Journal of Economic Biology* for October Messrs. Collinge and Shoebotham contribute a long article on the Apterygota (Thysanura and Collembola) of Hertfordshire, to which they have devoted special study. Before they commenced there appear to have been no records of these minute insects from the "county of Hertfordshire," but the authors are now enabled to enumerate four species of Thysanura and sixty-nine of Collembola.

To the *Anales* of the National Museum of Buenos Aires, ser. 3, vol. xiii., p. 317, Dr. F. Ameghino contributes a note on certain teeth from a cavern in Cuba, which are referred to a large monkey the dental formula of which is identical with that of the Cebidæ, but the cheek-teeth of which are stated to approximate to those of Old World monkeys and man. For this monkey the new generic and specific name of *Montaneia antropomorpha* is proposed. It is noteworthy that no wild monkeys are found in Cuba at the present day.

IN the October issue of the *Journal of Economic Biology* Prof. Hickson discusses the place of economic zoology in a modern university, and the best way of training students in that branch of science. After pointing out that there is a growing demand for the services of men capable of dealing with the problems of economic biology in a practical manner, the author observes that the qualifications usually associated with what is termed "a good field-entomologist" will not suffice, and that a man who aspires to a post of this nature must have a working acquaintance with parasitism, parthenogenesis, heredity, and embryology; while he should possess special knowledge of the Protozoa, parasitic worms, land and fresh-water snails, and, particularly, tracheate arthropods. Such a course of study "could be given in the zoological departments of the principal universities of our country without very much additional equipment or a very material addition to the numbers of the teaching staff. But in order that the student may have the opportunity of getting some training in the recognition of insect pests in the field, the work of the laboratory should be supplemented by some systematic teaching in connection with an institution of the nature of an agricultural college, in which access to growing crops may be facilitated."

THE question of the systematic position and feeding-habits of the African Jurassic genus Tritylodon, and its northern allies Plagiaulax and Ptilodus, is reopened by Dr. R. Broom in the October issue of the Proceedings of the Zoological Society. In the first place, the author has no doubt as to Tritylodon being a mammal, while as the only known specimen is from the Stormberg beds, it must be regarded as of Lower Jurassic, and not Triassic, age. As regards the affinities of the three genera, Dr. Broom refuses to admit that Mr. Gidley is justified in including them among the diprotodont marsupials, remarking that the dentition, both structurally and numerically, is of a different type, while the presence of a well-developed septomaxillary in the African genus suggests monotreme rather than marsupial affinities. It is also pointed out that there is a considerable probability of diprotodonts having originated in Australia. "In the present state of our knowledge it seems wisest to leave the Multituberculata as a distinct independent group with no very near affinities with the living monotremes, marsupials, or eutherians." As regards the food of these mammals, the author points out that fruits were non-existent in Jurassic times, while if, as he considers probable, Tritylodon and its relatives were carnivorous, they must have fed mainly on reptiles, which would require a type of dentition different from that of mammal-eating species.

A NOTE on a fungal disease of the blue pine, *Pinus excelsa*, reported from the Simla forestry division, is contributed to the *Indian Forester* (October) by the assistant to the imperial mycologist at Pusa. The chief object of the note is to establish the observation of infection proceeding from diseased to healthy roots, for which good evidence is adduced. The fungus is reported to be *Trametes pini*, for which such marked fungal development in the root, and infection from root to root, has apparently not been previously recorded.

MESSRS. FLATTERS, MILBORNE AND MCKECHNIE, of Longsight, Manchester, are issuing a quarterly publication of fifteen pages entitled the *Micrologist*. Part ii., issued October 1, contains two excellent articles, one on mounting microscopical objects in fluid media in cells, the other (by Mr. H. E. Hurrell) on the polyzoa and the methods of collecting and mounting them. It is well printed and illustrated, and contains a beautiful plate of five reproductions of photomicrographs of starch, volvox, hydra, &c.

A USEFUL list of pteridophyta for the Transvaal province is communicated by Mr. J. Burtt-Davy to the *South African Journal of Science* (October) on behalf of the late Mr. V. G. Crawley and himself. To make the list serviceable to teachers and students, brief diagnoses are supplied for the classes and genera, while analytical keys and localities are given for the species. Among the true ferns, *Cyathea Dregei* and *Mohria caffrorum* are two remarkable common species; *Oleandra articulata*, *Todea barbara*, and *Marattia fraxinea* are said to be rare. With respect to the number of species, Asplenium, Pellæa, and Gymnogramme are conspicuous genera.

MR. W. N. LUBIMENKO publishes in the botanical section (series iii., parts i.–ii.) of *Travaux de la Société des Naturalistes de St. Pétersbourg* a long paper (in Russian) in which he presents the results of experiments directed towards ascertaining the relationship that exists between the amount of chlorophyll present in a leaf and the energy of photosynthesis. In the summary it is stated that the minimum intensity of light required to start photosynthesis depends on the amount of chlorophyll, being less as the amount of chlorophyll is greater; also that as the amount of chlorophyll increases the energy of photosynthesis increases up to a maximum, and then decreases. It is further suggested that certain experiments indicate that photosynthesis proceeds in two stages; first, CO_2 is decomposed and O is liberated, then certain photochemical reactions lead to the transport and incorporation of organic material.

A CORRESPONDENT sends us examples of a monstrous carnation in which the inflorescences have produced no true flowers, but a superabundance of bracts. This

peculiarity in carnations and certain species of Dianthus was observed many years ago (see "Vegetable Teratology," p. 371, by M. T. Masters). An example is illustrated in the *Botanical Magazine*, Tab. 1622, in which one bud has developed into a perfect double flower, and several others are exactly similar to those sent by our correspondent. Earlier than this, Linnæus had met with a similar malformation, and given it the name of *imbricatus*. The distorted flower buds so nearly resemble ears of wheat that they are known as "wheat ear" carnations. It is not known what causes the suppression of the other parts of the flower and the increase in the number of bracts, but Masters pointed out that the condition is met with frequently in a species of Mœsa, in *Plantago major*, and in *Gentiana Amarella*.

Hitherto agricultural chemists have concentrated attention mainly on those constituents of the soil that are essential to the production of plant food, but recently attempts have been made to ascertain the effect of the non-essential or the rarer constituents. The investigations at Woburn are well known. Mr. Failyer, of the United States Department of Agriculture Bureau of Soils, has published (Bulletin 72) a number of analyses showing that barium is present in most soils in the United States, especially in soils derived from rocks containing barite deposits or from the Rocky Mountains. The quantity sometimes rose near to 0·1 per cent. Felspar is also a source of barium. It appears probable that the soil moisture, which plays a part in the nutrition of plants, contains barium salts, and cases are on record where barium has occurred in the plant ash. Its presence there would be injurious to animals, and may perhaps be the cause of some of the unexpected results occasionally produced by vegetation.

M. Aug. Chevalier, in a letter on his explorations in Upper Dahomey, published in the last number of *La Géographie* (October 15), mentions a curious phenomenon which he observed with respect to the Ouémé River. In its middle course, last May, he found during his stay of fifteen days that the stream ran continuously in a reversed direction, toward the head of the river. The gradient of its bed in this part is very small, and the upper reaches are completely dry during several months of the year, as is the case with most of the rivers of the central African plateau. The rainy season sets in earlier in the downstream part of the country and fills the empty channel, which then runs for a time both ways until equilibrium is established, after which the normal direction of flow is maintained. Similar abnormalities have been previously observed in some of the water-channels of the Kalahari desert in south-central Africa.

In Nature of October 20 (p. 503) reference was made to an article in the *Times* on the Norwegian expedition to Spitsbergen, which contained a somewhat detailed account of the discovery of a volcano of recent age in a branch of Wood Bay. It appears, however, that there is still some doubt about the age of the volcanic phenomena. The latest number of *La Géographie* (xxii., No. 4, October 15) includes a note on the results of the expedition by M. Charles Rabot, based on an article in the Christiania *Aftenpost*, sent to him by Captain Isachsen, the leader of the expedition, as the only official communication which has yet been published. On this authority the following reference is made in *La Géographie* to the discovery:—"Finally, round a branch of Wood Bay, Mr. Hoel [one of the geologists] has made the very unexpected discovery of an ancient volcanic development (*appareil*). Contrary to what has been announced from Spitsbergen correspondence published in Christiania journals, it does not date the actual epoch, and for a long time has not been the seat of manifestations. At present, upon the shores of Bock Bay the internal activity manifests itself only by the presence of thermal springs, of which the temperature does not exceed 28·5°." The scepticism respecting the earlier newspaper accounts of the volcano, alluded to in our previous note, was therefore not altogether unjustified. The full particulars of the discovery will be examined with keen interest by geologists and geographers.

The Bureau of Science, Department of the Interior, Manilla, has issued the annual report on the mineral resources of the Philippine Islands for the year 1909. It is thoroughly characteristic of American methods that the United States Government should have straightway set about fostering the development of the mineral industry of their first colony. The success that has attended this attempt is clearly enough indicated in the present report. The main product up to the present has been gold, the output of which for the year 1909 is valued at about 49,600*l.*; it shows an increase of 14 per cent. over that of 1908, in which year the output was about three times that of the year previous. Even more important from the point of view of general industrial development and civilisation is the increase in the production of coal; the total quantity raised in 1909 was 30,336 tons, an increase of 155 per cent. over the previous year, and more than seven times as great as the production in 1907. The entire production now comes from two mines on the island of Batan, one at the extreme east and the other at the extreme west of the island. The seams now worked are from 3 feet 4 inches to 5 feet 8 inches in thickness. The coal appears to be of Tertiary age; it is classed as sub-bituminous, is low in ash, and has given satisfactory results in raising steam. From the scientific point of view the chief interest of the report centres in a very brief sketch of the geology and geological history of the Philippine Islands.

The Meteorological Committee has issued a useful contribution to the study of the north-east and south-east trade winds of the Atlantic Ocean (Publication No. 203), comprising (1) an investigation by Commander Hepworth with the view of tracing any effect of the variations of those winds upon the temperature of the water in the North Atlantic; (2) a *résumé* of the meteorological data available for St. Helena, by Mr. J. S. Dines; and (3) a calculation, by Mr. E. Gold, of the relation between the periodic variations of wind velocity and of atmospheric pressure, with the application of the general theorem to the case of St. Helena. In Nature of December 21, 1905, Dr. Shaw directed attention to an apparent connection between the circulation of the atmosphere, as represented by the south-east trade wind, and the meteorological consequences in other parts of the world, and the present work may be considered as an attempt to identify that connection, to trace the links in the chain of cause and effect, and also to supply information available for meteorologists interested in the subject. In a very lucid preface summarising some of the results Dr. Shaw points out that the marine discussion of the south-east trade wind shows hardly any seasonal variation (possibly due to the peculiarities of the Beaufort wind-scale), while the results for the north-east trade show a marked variation very nearly complementary to that at St. Helena, where the anemometer record exhibits a regular mean variation (irrespective of direction) between about 14 miles per hour in May and 21 miles per hour in September. Dr. Shaw points out that Mr. Gold's solution, on dynamical prin-

.iples, of the origin of the diurnal variations of the trade wind over the South Atlantic gives results which are hopeful, but not final.

THE well-known observatory on Mount Vesuvius was founded in the days of the Kingdom of Two Sicilies, and was taken over by the Government at the time of the unification of Italy. The work that it has done under the direction of Prof. Palmieri, and latterly Matteucci, is well known; but in a plea put forward in the *Atti dei Lincei*, xix., 3, Dr. Carlo dei Stefani states that the institution has been hampered by the want of a more substantial subsidy from the State, and he further directs attention to the desirability of establishing a much more extensive institution for the study of Vesuvius in all its aspects. It is pointed out that since the observatory was founded every branch of science has advanced enormously, that the study of volcanoes plays an important part in geology and geophysics, and that Vesuvius, from its situation as well as from our intimate knowledge of its past history, offers exceptional facilities for systematic study. In such an institution the departments of geology, mineralogy, chemistry, and physics should all be represented on the staff.

THE geometry of the triangle occupies a somewhat unique position in mathematics, leading as it does to a large number of results which appear to be capable of being added to almost without limit, which do not require the employment of advanced methods for their study, and have the further interesting peculiarity—perhaps not altogether a disadvantage—that they can be studied without afterthoughts as to probable utilitarian applications. We have received two papers on this subject. One is by Mr. W. Gallatly (London: Francis Hodgson, price 2s. 6d.), dealing with Lemoine and Brocard points, angular and tripolar coordinates, pedal and antipedal triangles, the medial triangle, Simson's line, the orthopole, and orthogonal projection. The second, by Mr. W. H. Salmon, is a note reprinted from the *Quarterly Journal of Pure and Applied Mathematics*, dealing with the Omega and Omega-prime lines and the γ line. These lines are defined by the property that if O be any point in the plane of a triangle, and the lines OA, OB, OC be rotated through a constant angle, they will, for certain angles of rotation, meet the sides taken in order in three points lying on a straight line, these lines being the lines in question.

PROF. L. PALAZZO has sent us a copy of his "Misure Magnetiche fatte in Sardegna nel 1892," extracted from vol. xxiv. of the *Annali* of the Italian Meteorological Service. This volume belongs to the year 1902, but the chronological order has not been observed in the publications of the Italian Meteorological Service—some of which are much in arrears—so that an account is only now published of the magnetic survey of Sardinia made by Prof. Palazzo in 1892. Sixteen stations were occupied, the observations at which are described in minute detail, the results being embodied in a chart. No really large local disturbances were detected, but some minor disturbances were noticed, especially towards the north-west of the island. Besides a full description of the observational methods and reductions, there are descriptions, with plates, of apparatus for determining the temperature and induction coefficients of collimator magnets, with which very consistent results seem to have been obtained.

IN the May number of the International Bulletin of the Academy of Sciences of Cracow Prof. Smoluchowski, of the University of Lemberg, gives an account of some measurements he has recently made of the heat conductivities of fine powders, and the influence of the size of the grains and the state of the gas between them on the conductivity. His apparatus is in principle identical with that used by Kundt and Warburg in their measurements of the heat conductivities of gases. It consists of a thermometer the bulb of which is surrounded by a tube nearly concentric with it, the space between the bulb and tube being filled with the powder and connected to a Gaede pump, so that it can be filled with a gas or evacuated. Whatever the nature of the powder, the conductivity through the gas between the grains is found to diminish rapidly as the pressure of the gas is reduced, and for granular, as distinguished from spongy, powders its dependence on the pressure may be calculated by the aid of the kinetic theory of gases if the surface resistance, which depends on the mean free path of the molecules of the gas, is taken into account at the low pressures.

COPIES have reached us of the volumes of magnetic data recorded during 1905 and 1906 at the observatories of the U.S. Coast and Geodetic Survey. There are five of these observatories, viz. at Cheltenham, Baldwin, Sitka, Honolulu, and Vieques (Porto Rico). The Cheltenham volume is dated 1909, the others 1910. Thus the delay in publication seems hardly accounted for by the inclusion of two years' data in the same volume. The procedure followed and the mode of presenting the data are closely alike at all the stations. Full particulars are given of all the hourly readings and of the daily maxima and minima, but only the ten quietest days of each month are employed for deducing the diurnal inequalities. Each volume contains a table of the principal magnetic disturbances, and some of the curves showing them are reproduced on a reduced scale. Except at Cheltenham, the times shown on the curves are G.M.T., thus facilitating intercomparison, but the times of commencement, &c., given in the text are in local mean time. The stations are now all provided with a complete outfit of Eschenhagen magnetographs, including vertical force instruments. The troubles experienced—discontinuities in the trace, changes of scale value, drift of trace across the sheet, and general instability—are described in some detail, and though most prominent in the vertical force instruments, seem by no means confined to them. Even the declination instrument gave serious trouble at Baldwin, leading to considerable loss of trace. One cannot but experience a doubt whether a more stable and less sensitive type of instrument would not have been preferable, especially at the less accessible stations. In addition to other troubles, Sitka suffered from an outbreak of dry rot, which necessitated a large amount of internal structural alteration in the magnetograph room. This led, however, practically to no loss of trace, the magnetographs being accommodated during the alterations in a temporary building. In addition to magnetic data, there are particulars of the seismic movements recorded by seismographs, mostly of the Bosch-Omori pattern.

A LIST of observing stations and particulars of the apparatus employed in connection with the *Michael Sars* North Atlantic Deep Sea Expedition, 1910, has just been received. An article by Dr. Johan Hjort describing the work of the expedition is given in another part of the present issue.

MESSRS. HENRY SOTHERAN AND CO., 140 Strand and 43 Piccadilly, London, have issued a new classified catalogue (No. 709) of second-hand books on geology,

mineralogy, mining, and metallurgy, including the library of the late Prof. Hilary Bauerman, with a supplement of sets of periodicals and publications of the learned societies.

THE Cambridge University Press has undertaken the publication of a work entitled "Principia Mathematica," by Dr. A. N. Whitehead, F.R.S., and the Hon. B. Russell, F.R.S.; the aim of the work is to show the dependence of mathematics upon logic by deducing from purely logical premises the elementary propositions of various branches of mathematics. The first volume, on mathematical logic and prolegomena to cardinal arithmetic, will be published very shortly. The second volume, concerning the principles of arithmetic, is in the press. In the third volume the authors have dealt with measurement and the principles of geometry.

WE have received the first part of vol. xviii. of the Journal of the Royal Institution of Cornwall. The proceedings at the annual and spring meetings of 1909 are given at length. The annual excursion of 1909 is described, and the address of the president, Dr. Richard Pearce, at the spring meeting in 1909 is printed *in extenso*. Among papers read at the meetings during 1909 may be mentioned:—King Arthur's Hall on Bodmin Moor and some Irish circles, by Mr. A. L. Lewis; the fauna of St. Ives Bay for 1908, by Mr. R. Vallentin; and the invertebrate fauna of Cornwall—Hymenoptera Entomophaga and Hymenoptera Aculeata, by Mr. W. A. Rollaston. The volume also contains meteorological tables for Cornwall for 1909.

OUR ASTRONOMICAL COLUMN.

FIREBALL ON NOVEMBER 2.—A brilliant fireball was observed on Wednesday, November 2, 7.46 p.m. It passed from east to west over the English Channel, and fell from heights of 84 to 26 miles. As seen from Cornwall and from the north of France, as well as from ships in the Channel, the meteor was a splendid object, yielding a brilliant light, as though the moon had broken out from clouds. The stream of aërolites from which the phenomenon was directed has its radiant point in Aries, and further observations are desirable.

ROTATION OF THE MOON.—A correspondent has been puzzled by the perennial perplexity of non-mathematicians as to how the moon can be said to rotate when she always presents the same face to the earth. The answer, of course, is that as we prove the rotation of the earth by the fact that any meridian, such as that of Greenwich, completes its circuit with respect to any fixed star in the course of a *sidereal* day, so also the similar consideration shows that the moon rotates on her axis in $27\frac{1}{3}$ days, during which time she also completes her circuit about the earth with respect to the stars.

The moon's equator is not quite circular, since her figure may be considered as possessing a solidified tidal inequality of shape. Laplace examined the mechanical results of this condition of affairs, and showed that the moon would oscillate slightly about a mean position relatively to the earth. This is called the physical libration of the moon, and in consequence of its existence we see slightly more than half of the moon's surface.

It is probable that the moon once rotated more rapidly on her axis, and that her rotation was reduced by tidal friction to its present magnitude. The transition from a slow rotation to a libration would present a problem of considerable mathematical difficulty. We can, however, see what would be the several stages through which the changes would pass. There would first be unequal speed in the several parts of the rotation; this inequality would increase until at two moments in one rotation that rotation would nearly cease; then there would occur an actual stoppage, and the direction of motion would reverse itself for half a rotation, constituting a very large libration; finally, the amplitude of libration would diminish to its actual insignificant magnitude.

EPHEMERIS FOR HALLEY'S COMET.—Dr. Ebell publishes a continuation of his ephemeris for Halley's comet in No. 4450 of the *Astronomische Nachrichten*. The ephemeris covers, in four-day steps, the period November 5 to December 31, and shows that the comet is now travelling in a south-westerly direction through Corvus; its magnitude is about 15·5.

SELENIUM PHOTOMETER MEASURES OF THE BRIGHTNESS OF HALLEY'S COMET.—Observing at the Illinois University Observatory, Mr. Joel Stebbins measured the brightness of Halley's comet with his selenium photometer on fifteen occasions during May, and now publishes the results in No. 2, vol. xxxii., of the *Astrophysical Journal*. The selenium cell was attached to the 12-inch refractor, and, through a diaphragm, light from a circle 7 minutes of arc in diameter was admitted to it; Mr. Stebbins suggests that eye-estimates of the comet's brightness never included a larger area. The cell is known to be especially sensitive near the red end of the spectrum, and it is supposed that, unless the spectrum of the comet was very peculiar, the systematic error of these observations would be less than visual comparisons of a luminous surface with a point source of light, such as a star; extra-focal images of stars were used in the comparison, and in the morning observations the brightness of the sky was measured and taken into account in adopting final values for the comet's brightness. The range of the latter is shown by the following values, given in magnitudes:—May 3, 2·0; May 11, 0·6; June 1, 3·6. The second value, 0·6, is vitiated by bad observing conditions, but Mr. Stebbins states that the comet became brighter than the first magnitude, although it never reached magnitude 0·0.

THE APPARENT DIAMETER OF JUPITER.—An earlier discussion of the observations of an occultation by Jupiter, made at the Zô-sè Observatory on May 21, 1908, led to the conclusion that the apparent diameter of the planet, as generally adopted, should be diminished; the occulted star was BD. $+19°$ 2095.

In No. 4450 of the *Astronomische Nachrichten* Father Chevalier, director of the Zô-sè Observatory, suggests that the observational results were not sufficiently certain to have such an important conclusion based upon them.

Attempting to determine more trustworthy data, he measured a photograph of the planet taken on May 19, and determined the corrections to the tabular place. Then applying these differences he found the position for May 21. This gave the position-angle of the star as $140° 23'$ and its distance from the centre of Jupiter as $18·7''$, a value greater than the semi-diameter of the planet. It is difficult to reconcile this result with the data for the occultation, and Father Chevalier urges that the observations made at other observatories should be closely examined and discussed from this point of view. A number of discussions such as he now publishes would possibly elucidate the matter

CURVED PHOTOGRAPHIC PLATES.—In No. 161 of the Harvard College Observatory Circulars Prof. E. C. Pickering describes some interesting experiments made for ascertaining the practical efficiency of curved plates in celestial photography.

With the 16-inch Metcalf telescope employed, the difference in focus between the edge and the centre of the plate is only 0·8 mm., but the experiments show that the bending of the plates to the focal curve is advantageous, while there is little likelihood of counterbalancing disadvantages.

Several methods were tried, such as holding the ordinary photographic plate against a properly curved concave surface by means of mucilage, &c., but it was found that the most successful method was to have the space between the plate air-tight, and then to exhaust it by means of a pump. Reproductions of actual photographs illustrate the gain in definition over the whole plate.

THE "MICHAEL SARS" NORTH ATLANTIC DEEP-SEA EXPEDITION, 1910.

IN the month of August last year, Sir John Murray approached me with the liberal offer of defraying the expenses of a deep-sea expedition to the Atlantic Ocean, provided the Norwegian Government were willing to lend their research-vessel, *Michael Sars*, for the purpose. Sir John Murray wished to ascertain whether the appliances and instruments used by the *Michael Sars* for her work in the Norwegian Seas would yield new information in the Atlantic. It was, besides, considered desirable to examine parts of the Atlantic that had previously been only very slightly explored. The Norwegian Government at once signified its willingness to accept this proposal, and I accordingly employed the past winter in making preparations for the expedition, assisted by the captain of the vessel, Mr. Thor Iversen, Prof. H. H. Gran, who agreed to lead the investigation of phytoplankton, and Mr. Helland Hansen, who took charge of the hydrographical researches. For my own part, I decided to cooperate with Mr. E. Koefoed, and to devote myself especially to zooplankton and the study of the bottom-fauna.

The expedition left Bergen at the end of March, arrived at Plymouth—where it was joined by Sir John Murray—and then followed the coasts of Europe and Africa down to Cape Bogador, carrying out special investigations in the Bay of Biscay, the Bay of Cadiz, and the waters between the Canary Islands and Africa—thirty-four stations in all. It next undertook a section into the Sargasso Sea, and after touching at the Azores, proceeded right across the Atlantic to St. John's, Newfoundland (forty stations). From there a section was taken to the south coast of Ireland (twenty-two stations), and, finally, we concluded our investigations by examining the waters between Scotland and Rockall and between Scotland and the Faroes—that is to say, north and south of the Wyville Thomson ridge—so as to study the influence exerted by the Atlantic Ocean upon the Norwegian Sea. The route of the expedition will be seen on the accompanying sketch (Fig. 1).

During this cruise we endeavoured, so far as time permitted, to undertake hydrographical and plankton investigations simultaneously, and we further carried out a considerable number of hauls with the trawl.

The large number of observations and specimens thus secured can, naturally, not be fittingly described before being systematically studied, and it is accordingly only possible as yet to furnish information regarding their nature and extent.

HYDROGRAPHICAL INVESTIGATIONS.

Hydrographical investigations have been carried out at about 110 stations. The temperature readings were taken with Richter's reversing thermometer and Nansen's thermometer, while the water-samples were collected by means of Ekman's water-bottle and the Petterson-Nansen isolated water-bottle. At most of the stations the temperatures have been recorded by two thermometers simultaneously at each depth, no fewer than 519 simultaneous readings being taken with the same two thermometers. The corrected temperatures gave an average difference of 0·01° Centigrade.

The difference between the two thermometers was :—

In 168 cases	0·00°
In 231 ,, ...	0·01°
In 84 ,, ...	0·02°
In 36 ,, ...	0·03° or over.

A fair number of simultaneous observations have been made with the reversing thermometer and Nansen's thermometer in the isolated water-bottle, with the view of observing the adiabatic effect by means of the difference in pressure. Besides the temperature readings, we have taken water-samples from all depths to determine the salinity and specific gravity, and we have endeavoured to get an exactitude in the determinations of salinity of 0·01–0·02 per mille, and in the density *in situ* an exactitude of 1–2 in the fifth place of decimals. On these lines the investigations have been carried out along the whole route of the expedition. We have, further, procured about 100 large water-samples from different stations and depths, for the purpose of determining the quantitative occurrence of nitrogenous substances, particularly ammonia.

The determinations from the deepest layers (down to 4950 metres) have given very uniform results, with a temperature of 2·48 C. It has been found that there is a very faint increase of temperature near the bottom at great depths, due, possibly, to the conduction of heat from the interior of the earth or a radium effect. In the upper layers conditions have varied considerably at times, especially in the neighbourhood of the Gulf Stream area and in the western portion of the North Atlantic. Here our investigations furnish apparently a number of new and interesting results, which, however, it is impossible to do more than

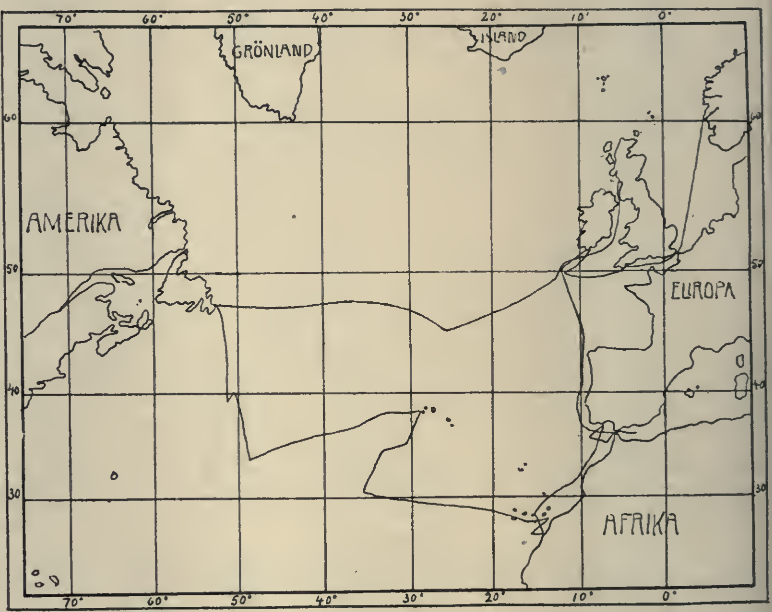

FIG. 1.

allude to before the water-samples have been thoroughly examined.

Surface temperatures have been recorded every hour during nearly the whole cruise, while every two hours a water-sample has been taken from the surface with particulars of the different meteorological conditions (wind, barometer, temperature of the air, humidity, and cloudiness). Altogether we have about 2500 water-samples and about 3000 temperature readings.

Several series of direct-current measurements have been made with Ekman's propeller current measurer. In the Straits of Gibraltar the current was so strong that we encountered no small difficulty in regard to anchoring. However, we succeeded in the course of a day in obtaining altogether seventy good measurements from eight different depths between the surface and the bottom. There were considerable tidal fluctuations both in the west-going surface current and in the deep east-going current; simultaneously with the fluctuations in the strength of the current the boundary between the two streams shifted upwards and downwards, as clearly appears from repeated series of temperatures and water-samples. The boundary lay at a depth between 50 and 100 fathoms below the surface. Velocities of four knots or

more were on several occasions recorded in both the surface current and the undercurrent; in the majority of cases, however, the velocity varied between 1 and 2½ knots.

On the slope south of the Azores the *Michael Sars* was anchored in 500 fathoms. Here about ninety current-measurements were made at different depths. In the deep sea between the Azores and the Canary Islands a series was taken right down to 2000 metres, from the vessel while under slow, steady drift, with one of the large tow-nets out as a drift-anchor. These measurements also show considerable fluctuations, which are apparently connected with tides. Similar investigations with modern methods have never been undertaken before either in deep water or in the Straits of Gibraltar.

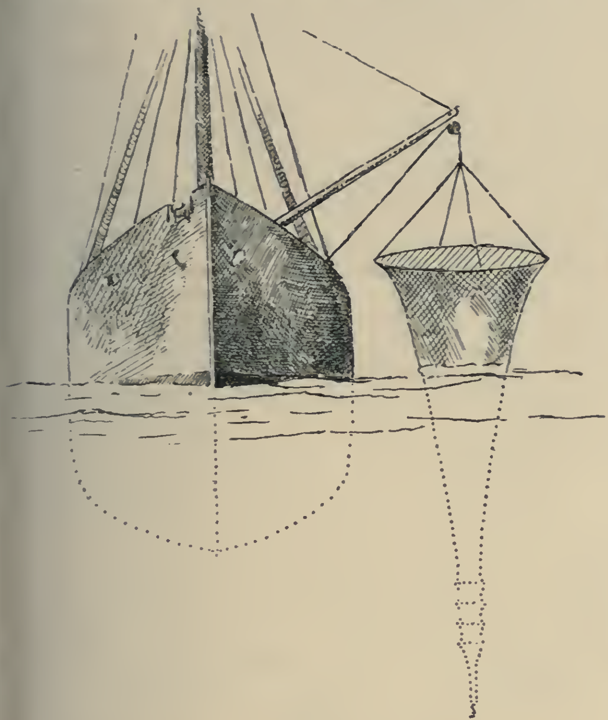

FIG. 2.

A number of measurements of light were also made in the ocean south and west of the Azores. Mr. Helland Hansen has constructed a new photometer which worked well; he determined the quantity of light by the aid of panchromatic plates with and without gelatine colour filters. The investigations showed a great influence of light rays at 100 metres, red being the weaker, and blue and ultra-violet rays the strongest; at 500 metres blue and ultra-violet rays were still found, and even at 1000 metres the influence of the ultra-violet rays was clearly evident. No trace of light could be noticed on the plates at 1700 metres, after an exposure of two hours at noon with a clear sky.

PHYTOPLANKTON.

Vertical hauls have been undertaken at various depths, at fully forty stations, with a fine-meshed Nansen closing-net, our object being to collect material for studying the vertical and horizontal distribution of peridinæ and diatoms in the Atlantic Ocean. We specially aimed at obtaining material for comparing the plankton of the coast-banks with plankton from purely oceanic waters, as also for comparing subtropical and boreal conditions of existence. The coast-banks off Ireland, Cadiz Bay, the west coast of Africa, and the Newfoundland banks have a characteristic flora which is sharply marked off from the oceanic flora, rich in species but poor in individuals, which is met with in the central parts of the Atlantic Ocean, especially the Sargasso Sea south of the Azores.

Largely owing to Lohmann's interesting researches in the Mediterranean, we arranged to devote a considerable part of our work to the study of those organisms, especially Coccolithophoridæ and the naked flagellates, which pass through even the finest silk net. These organisms have been partly collected by filtering sea-water through sand filters and partly by employing a large centrifuge driven by a small steam winch. Altogether we have employed the centrifuge in the case of about sixty of these water-samples; and, by means of a suitable contrivance, Prof. Gran was able to examine these samples on board in their living state, both in regard to quality and quantity.

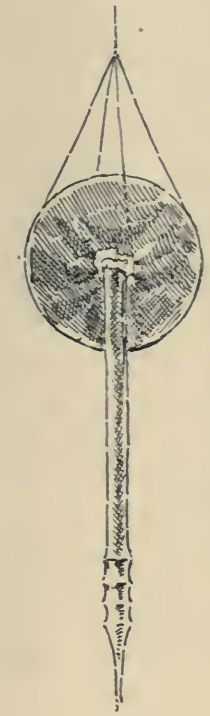

FIG. 3.

Examination showed a large number of new forms, partly belonging to quite new types, which will be described by Prof. Gran. In the central oceanic parts of the Atlantic Ocean these small organisms were found to occur in numerous forms and in such large quantities that they exceed in volume the plants obtained through the medium of the silk nets. In the neighbourhood of the European coast-banks the number of species was far smaller, but the quantity of individuals was particularly large. Thus we secured in a single sample more than 200,000 individuals per litre of one species alone. On the coast-banks off Newfoundland and off Ireland the peridinæ far exceeded in volume the Coccolithophoridæ.

Altogether the samples from the more northerly waters show a greater quantity of plants than the subtropical portion of the ocean. The material will likewise furnish information with regard to the distribution of phytoplankton in relation to depth. In the more northerly waters its range is limited to a thinner, less deep-reaching layer than in the more southern portion of the area of investigations.

ZOOPLANKTON.

For the study of smaller plankton animals, of the size of copepods, for instance, we employ a vertical closing-net, one metre in diameter, with rather coarser silk. With this we took samples at various depths and at many stations.

However, I perceived from the very first that an appliance of this sort would not be able to afford us much information regarding the occurrence of the larger pelagic animals, such, for instance, as cephalopods, decapod crustaceans, and deep-sea fishes. Both the *Challenger* and *Valdevia* expeditions employed, as will be remembered, a big tow-net, with which they made many vertical hauls from great depths to the surface of the sea. By this means they caught a certain amount, though by no means a

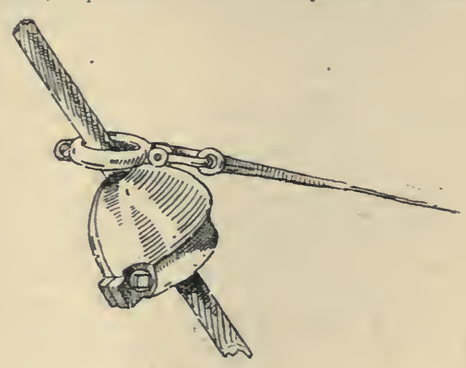

FIG. 4.

particularly large quantity, of fish in proportion to the number of hauls; and they naturally obtained but little information regarding such questions as the depth at which the animals live, and their vertical wanderings by night and day. These questions seemed to me to be of special interest at the present juncture, and accordingly an essential part of the work of our expedition was directed towards their solution. We first constructed some large nets of 3·25 metres diameter, partly of coarser silk and partly of prawn-net, arranged to close on the principle of Nansen's closing net (see Figs. 2 and 3). With these we made several successful hauls at various depths, and obtained sufficient catches of the commonest forms to enable us to determine more approximately the actual depth at which they occur. Nevertheless, we soon discovered that even these large nets yielded merely an incomplete collection of the fauna, since many species occur far too sparsely to be caught with vertical hauls. It was therefore found necessary to employ large horizontal-fishing appliances and to make hauls of considerable length.

Such hauls would, however, take an unduly long time, if they were to be carried out singly at the same station, for hours in succession, at different depths. It was, therefore, particularly desirable to drag a number of appliances at several depths simultaneously. The appliances had in this case to be fastened to one or two wire ropes, as one cannot tow many wires at the same time. The technical difficulty now presented itself that long lengths of wire get twisted, when towed, and consequently destroy the appliances or displace their position in the water. We solved this by an arrangement, shown in the accompanying figure (Fig. 4), by which a shackle to which the appliance is fastened moves freely round the wire. By this means it became possible to have no fewer than ten appliances out simultaneously from two wires, as shown in the figure (Fig. 5). Here we see a series, consisting partly of nets, partly of Dr. C. G. Joh. Petersen's young-fish trawls, in use at the following lengths of wire: 0, 100, 200, 300, 600, 1000, 1500, 2000, 2500, 3000 metres. The total number of these towing stations exceeded thirty.

The material obtained in this way was very large indeed. From the same station hundreds of pelagic deep-sea fishes and litres of large decapods, medusæ, &c., were secured. All the same, the hauls showed that the material was not by any means too large, since right up to the very last haul we continued to capture a few species of pelagic fishes that had not occurred in any of the previous hauls. The largest net, in particular, worked splendidly. We have thus discovered quite a number of species of pelagic deep-sea fish not previously described.

As there were so many stations, and we fished in widely differing waters and at all hours of the day and night, a comparison of these catches with each other will afford much information concerning the geographical distribution of the different species, as well as regarding the depth at which they occur by day and by night, and so on. The catches show that the hauls have much in common, and we may accordingly assume that they are in the main representative of the depth in which the appliances have been towed; and it is further extremely satisfactory to note that the experiences gained from these hauls and from the vertical closing-net are in close accordance.

It is too soon yet, and, moreover, would take too long, to describe in full the results of our experiences. I will confine myself, therefore, to mentioning that everywhere in the Atlantic Ocean, from the Wyville Thomson Ridge to the Sargasso Sea, there appears to be, at depths below 400 metres, a consistently uniform fauna of small, chiefly black pelagic fish, large red crustaceans, numerous medusæ, &c., a fauna which, in any case so far as the fishes are concerned, is probably also shared by other oceans, and which presents the same variety of form that the *Valdivia* expedition, for instance, has found in the Indian Ocean, and the *Challenger* in the Pacific. In the upper layers, at depths less than 400 metres, we have discovered numerous younger stages of fish that are not as yet determined, mostly of transparent, colourless form, such as Leptocephali, to take merely one example.

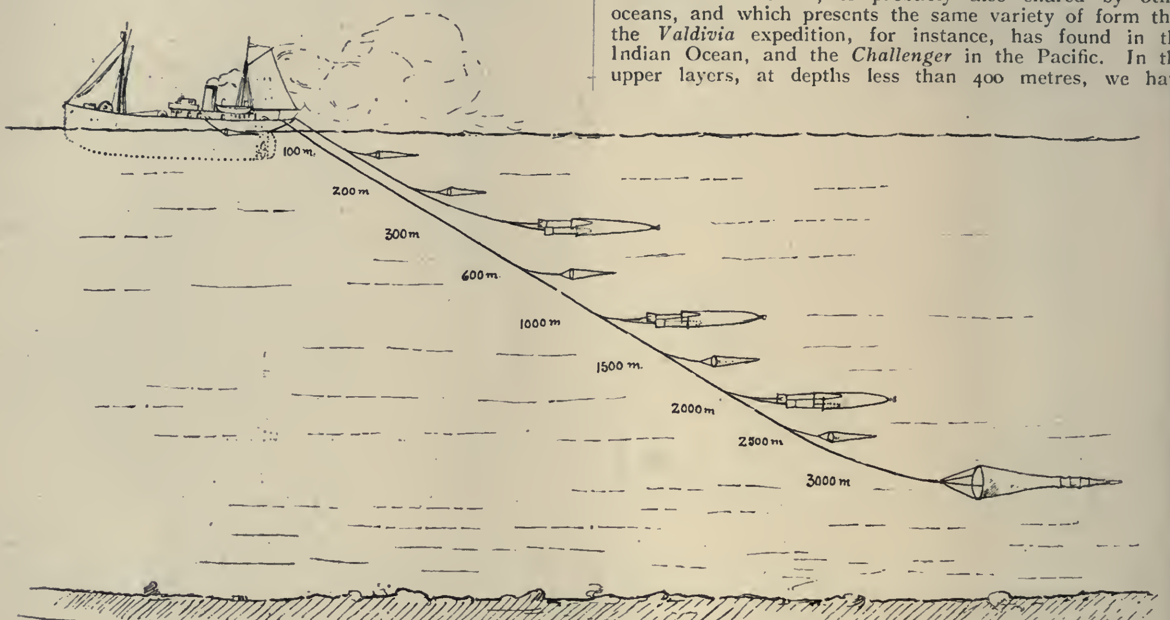

FIG. 5.

TRAWLINGS.

During previous expeditions in the Atlantic Ocean a great number of hauls have been undertaken either with the dredge or with small trawls. There was, therefore, no pressing necessity for the *Michael Sars* to investigate the bottom-fauna of the Atlantic, more particularly as hauls of this nature require a considerable expenditure of time, and could therefore with difficulty be combined with our exacting programme of hydrographical and plankton investigations. It was of interest, on the other hand, to try whether a large-sized model of the ordinary otter-trawl (with 50 feet of head-rope) would yield new results. During my previous researches I had succeeded to my satisfaction, and had secured very good catches, by making use of a trawl of this kind at depths down to 1000 fathoms. It was, in my opinion, especially desirable to employ this appliance along the Continental slope from the Wyville Thomson ridge southwards to the tropical coast of Africa, so as to ascertain the composition of the fauna on this long stretch at depths varying from 500 to 1600 fathoms.

Besides, I considered it of the utmost interest to attempt some hauls far out from the coast-banks on an oceanic deep plain with depths descending to 3000 fathoms. Altogether we have carried out twenty-two hauls at various depths with this large trawl.

It will be seen that our trawl had a greater capacity than any of the appliances previously employed, and that it can therefore, without doubt, be recommended for investigations of the deep-water fish-fauna. This is especially the case where it is requisite to have many individuals for examination. For invertebrate organisms, on the other hand, smaller and more handy appliances may be preferable.

Essentially new types of fishes the trawl cannot be said to have taken. But the material we possess furnishes a good picture, especially of the uniform fish-fauna to be met with along the slopes of the coast-banks of Europe and Africa from the Wyville Thomson ridge down to Cape Bogador, and it also shows clearly the sharp transition from the southern to the northern side of the Wyville Thomson ridge, which the *Triton*, the *Knight Errant*, and my own investigations, amongst others, had previously demonstrated.

The hauls at great depths (about 5000 metres) were no doubt few, perhaps too few; but they accorded with each other and with the hauls made by previous expeditions, more especially those of the *Challenger*, *Travailleur*, and *Talisman*, in indicating that the actual eastern deep-ocean plain of the Atlantic is especially poor in all kinds of higher organisms and particularly in fish. It might, by some naturalists, be regarded as a desert region. A fuller discussion of our observations must, however, be reserved for a more comprehensive publication.

JOHAN HJORT.

THE ASSOCIATION OF TEACHERS IN TECHNICAL INSTITUTIONS.

THE annual meeting of the Association of Teachers in Technical Institutions was held at the Northern Polytechnic, London, on Saturday, November 5. In moving the adoption of the annual report of the council, Mr. J. Wilson (Battersea Polytechnic), the retiring president, stated that any further extensive progress in the general technical and scientific education of this country depends upon the adoption of certain educational reforms, for most of which public opinion is now ripe. These reforms may be briefly summarised as follows:—(1) elementary education to be more practical or constructive; (2) compulsory attendance at day or evening (preferably day) continuation schools, with a limitation of the hours of labour of adolescents; (3) the institution of "technical-secondary" schools; (4) the linking of the elementary school through the continuation and secondary school to the technical school; (5) the increased provision of scholarships, with adequate maintenance grants, so that the qualified day and evening technical student may receive the highest possible technical and scientific training. These suggested reforms are all quite practical, and their adoption would entail but relatively little strain upon the financial resources of this country, while the commercial and educational results would be of incalculable benefit.

Attention was directed to the promise held out in the Prefatory Memorandum to the recent Board of Education regulations for technical schools, that the Board would take action, in the near future, with respect to certain of the more pressing of the educational reforms just referred to. A significant statement in the memorandum, relating to the payment of grants for technical instruction to institutions of university rank, together with the recent formation of a "University Branch" at the Board of Education, emphasises the modern tendency towards bringing the English universities within the purview and influence of the national educational authorities The hope was expressed that this would result in the opening wider of the doors of the university to the community, and a closer connection of the universities with all phases of educational effort in this country.

The recent regulations of the Board of Education respecting the registering of the attendance of day and evening students at technical institutions were criticised adversely, inasmuch as by considerably increasing the time and attention to be devoted by the teacher to the merely mechanical work of registration, they inevitably detract from the efficiency of the teaching as a whole.

In discussing the first volume of the minutes of evidence submitted to the Royal Commission on University Education in London, Mr. Wilson stated that in this evidence there appears vague and unjust criticism of the higher work of the London polytechnics, generally based upon want of knowledge of the work these institutions are now doing.

The president of the association for 1910–11 is Mr. Barker North, of the chemistry and dyeing department, Bradford Technical College.

METEOROLOGICAL RELATIONSHIPS.

PROF. H. HILDEBRAND HILDEBRANDSSON is continuing his important series of papers on the centres of action of the atmosphere, and the fourth communication, recently received, is entitled "Sur la Compensation entre les types des Saisons simultanés en différentes régions de la Terre" (*Kungl. Svenska Vetenskapsakademiens Handlingar*, Band 45, No. 11). In his third paper he suggested that the principal cause of the different types of seasons depended very probably on the condition of the ice in the polar seas, and the evidence he brought forward was such as to show that this view had very much in its favour. In the present communication he makes a closer study of these compensations between the types of simultaneous seasons in both winter and summer seasons, and extends his researches to North America. He further directs attention to some analogous results which he finds exist in the southern hemisphere. Thus he finds both in winter and in summer that there occurs an opposition between the north and south of both Europe and of North America, and also probably between the sub-polar regions and sub-tropical regions of the southern hemisphere. There is also, in general, an opposition between the north of Europe and Siberia.

Special attention is directed to some regions where this opposite nature of seasons is in some years less pronounced, and Prof. Hildebrandsson points out that these districts are intermediate between the main centres of typical action, and are therefore dependent on the intensity of the latter. This communication is accompanied by several plates of curves, and these should be closely studied in connection with the text. There is little doubt that these researches will in time open up a field for the future forecasting of seasons, but it is important to bear in mind that so intimate are the meteorological associations between very widely separated regions on the earth, it behoves the investigator to take a very broad view of the subject, and not confine himself to one small portion of the earth's surface.

Mr. E. T. Quayle, of the Australian Commonwealth Meteorological Bureau, has recently (Bulletin No. 5, March) published the results of his investigations in relation to the possibility of forecasting the approximate rainfall for northern Victoria. At the outset he states that it has long been his conviction that ordinary statistical methods must prove inadequate, and that they do not enable the essential differences between the weather of successive years to be grasped. In his study of the storm systems as they have affected Victoria he has made a classification of them, and on this he bases his method of forecasting. The storms which affect Victoria and bring the rain belong to two main systems, one called "Antarctics," which originate in the southern seas, and the other called "Monsoonals," which are of tropical origin. The first-named he divides into two classes:—(*a*) Antarctics, when their centres are too far south to be identified; and (*b*) Antarctic cyclones, when their centres can be located inland or over Bass Strait. The monsoonal low depressions he divides into three groups:—(*a*) monsoonal troughs; (*b*) monsoonal dips; and (*c*) monsoonal cyclones.

By the use of isobaric charts the number of occurrences of each type of disturbance was taken out for each month for the years 1888 to 1909. As the northern districts of Victoria receive most rain chiefly from monsoonal de-

pressions or the fronts of well-developed Antarctics, a typical rainfall curve of the northern areas was constructed. Thus for each half-year the low- and high-pressure systems passing Victoria were counted, and alongside the numbers thus obtained were placed the figures for the rainfall over the northern areas and the mean air pressure and temperature for Melbourne. The comparison brought out the result that an excess in the number of summer monsoonal disturbances was followed by an excess in the winter rainfall in seventeen cases out of twenty-two.

Mr. Quayle then evolves a rough rule for predicting the approximate winter rainfall over northern Victoria, giving the weights of two, one and one to the number of monsoonal disturbances, mean pressure, and mean temperature, respectively, for the preceding summer. Noting the coincidences of sign only in the values he evolves for the calculated winter rain, he finds that they are in agreement with those for the actual departures from normal of the winter rains nineteen times out of twenty-two, and in serious agreement in two cases only. It is unfortunate that, owing to lack of daily isobaric charts, the period could not have been extended over more years; nevertheless, the system may be used tentatively, and the results will be watched with interest.

THE LATITUDE OF ATHENS.[1]

In the volume referred to below M. Eginitis describes the varied activities that exercise the staff of the National Observatory of Athens and of the smaller institutions that his zeal has called into existence and made to yield results useful to science, both as regards seismology and meteorology. It seems not a little strange to find well-remembered names like Thebes, Sparta, Naxas, Samos, and many others famous in the past, figuring in this list, and playing a new *rôle* by contributing climatic observations made on approved lines with modern instruments. Of the last mentioned of these stations, that on the island of Samos, the author remarks, "malheureusement, elle a été complètement détruite, le jour du bombardement de cette île, en 1908, par la flotte turque," recalling a struggle which seems more in keeping with its ancient history than its effort to accumulate meteorological observations.

But the real serious piece of work here described is the attempt to determine the latitude of Athens, a problem that interested Ptolemy, who recorded the value 37° 15′, placing the city some 45 kilometres south of its true site, even when allowance for all known sources of error is made, a larger error than is usual in similar determinations in that age. But error seems to cling to this unfortunate coordinate, for M. Eginitis informs us that the latitude for the Pantheon given in the "Connaissance des Temps" is about 6″ too small. In striving for the nicest accuracy, the director has found the problem to be one of extreme difficulty. He has employed two methods and two instruments, and the results do not coincide. He has employed the Horrebow-Talcott process, carried out by means of an instrument originally intended for a meridian circle, but by removing the microscopes and adding a level, adapted to that particular form of observation. Later, through the generosity of M. Syngros, he was supplied with a modern and excellent meridian circle by Gautier, the construction of which was supervised by M. Lœwy. This instrument was used for determining the zenith distances of both circumpolar stars and stars of known declination, the zero being derived from nadir observations only.

The interest in the discussion consists in the different values obtained after reversing the instrument. The difference is constant and rather larger than has been noted elsewhere. Like the R-D term in similar inquiries, it refuses to yield a satisfactory explanation, however ingeniously solicited. There is no attempt to determine the actual variation of latitude, though the observations extend over a considerable period, nor, as we think, is sufficient attention paid to the possible effect of a "magnitude equation." The inquiry is of a purely instrumental character, and is directed mainly to the legitimacy of employing an arithmetic mean of the values obtained in the two positions of the instrument. If this conclusion is warranted and offers the only possible means of correctly determining the latitude, M. Eginitis is justified in insisting upon the necessity of reversion and of providing for the operation in the construction of the instrument. But as the director promises further experiments and a more rigorous attempt to eliminate all possible sources of error, it will be desirable to pause before offering any criticism or accepting the result as final.

EDUCATION IN TECHNICAL OPTICS.

The reawakening of the British optical industry which began with the first years of this century brought with it a demand for the provision of special technical education in optics. The Northampton Polytechnic Institute, from its situation in Clerkenwell, where much of the London optical industry is centred, was particularly suited as a centre for such work, and optical classes were begun there as a branch of work in general physics. The optical trade, however, regarded these classes as being of little value, and in 1902 a new syllabus was adopted and a special department of technical optics was instituted. Since that time this department, under Mr. S. D. Chalmers, has developed very considerably and done much useful work for both day and evening students, but the scope and value of this work has been continually hampered and further development has been completely blocked by want of proper space and equipment. This unsatisfactory state of affairs has been fully realised, and the governors of the Northampton Institute have acquired the necessary land on a site opposite the institute, and have had plans prepared for a complete "Opto-technical Institute"; for the erection and equipment of the building they are, however, dependent on a grant from the London County Council.

The County Council or its predecessors in authority, the School Board, has been repeatedly approached in this matter. A deputation from the Optical Society in 1902 led to a grant which resulted in the establishment of the optics department at the institute; for a time this was supplemented by a grant from the Company of Spectacle Makers, but this has subsequently been replaced by a trade fund, collected principally by the efforts of Mr. J. Aitchison and administered by the Optical Society. In 1905 the Optical Convention sent a deputation to the London Education Committee; this deputation was headed by Dr. R. T. Glazebrook, and included a large number of influential men connected with the science or industry of optics, but, although favourably received, no practical steps resulted for five years.

Now, however, there appears to be a definite prospect that this want of our optical industry may soon be met in an adequate manner. This is indicated by a circular letter issued a few weeks ago by the L.C.C. Education Officer to members of the optical trade in London. In this letter the members of the trade are asked to state their views as to the need for an Opto-technical Institute in London, and to indicate to what extent they or their employés would take advantage of any facilities provided, and what benefits they would expect to derive from such teaching. The letter concluded by inquiring whether, in the opinion of the trade, an expenditure of about 30,000*l.* for a building for such a purpose would be justified, and the general scheme of the new institute as proposed by the Northampton Institute is indicated. This comprises a series of large teaching laboratories and lecture-rooms for instruction in all branches of optics, lens-working and general instrument design and construction being provided for, as well as the theoretical and experimental branches of the subject. The new institute would accommodate 300 to 400 day and evening students, complete day courses as well as evening classes being contemplated.

Fortunately there is every reason to believe that the optical trade will respond to this circular letter in a manner which will fully justify the London County Council in proceeding at once with a scheme which is really of

national importance. An opening meeting of opticians and those interested in optics was called by Mr. J. Aitchison at Anderton's Hotel in Fleet Street on October 17, and an attendance of 300 enthusiastically and unanimously affirmed their approval of the London County Council scheme. This was probably the largest, and certainly the most unanimous, optical meeting ever held in London; all the speakers emphasised the need for close cooperation between science and industry in the optical more than in most other industries, and the consequent need of the best educational facilities for masters and workmen. It is clearly recognised—not in this country alone—that the British optical industry has made and is making a very great effort to regain lost ground; such names as Grubb and Hilger show that there is even now British leadership in some fields of optics. With the help of such schemes as that of the London County Council these fields might well be extended.

THE CRYSTALLOGRAPHY OF HÆMOGLOBINS.[1]

CRYSTALS of oxyhæmoglobin differing greatly in character are figured in every text-book of physiology; but in the absence of specially skilled study by a crystallographer it has always seemed possible hitherto that the differences observed might be dependent on polymorphism, differences in water of crystallisation, effects of environment, or on chemical change, and that hæmoglobin, from whatever source obtained, was essentially one and the same substance. Hüfner's observation that all hæmoglobin solutions giving the same extinction coefficients in the spectrophotometer showed the same capacity for oxygen appeared to support such a view, although it could also be interpreted as showing merely, what was already probable on other grounds, that the hæmatin portion of the molecule was identical in all cases.

Profs. Reichert and Brown, regarding crystalline character, when interpreted with care and knowledge, as a trustworthy criterion of identity or non-identity, have prepared crystals of oxyhæmoglobin and its near allies from some two hundred species of animals, and subjected them to minute crystallographic analysis. Their observations show beyond doubt that hæmoglobin exists in almost innumerable varieties, each of which is more or less characteristic of the species from which it was obtained. In view of the ease with which oxyhæmoglobin undergoes chemical change, the demonstrated impossibility of purifying it by recrystallisation without the occurrence of such change, the effects of admixture with other substances on crystal form, and the difficulties of crystallographic interpretation, it is inevitable that some reserve should be felt in accepting all their conclusions in detail, but the main facts presented can hardly be interpreted otherwise than in the way suggested by the authors.

It is, however, much to be regretted that they have not described the spectroscopic characters of the crystals studied in each case, since the omission of this information leaves it open to doubt whether the material examined was always what it was taken for. In the absence of spectroscopic evidence, their statement that the blood of the horse, python, and many primates, including man, contains in the same individual two different kinds of oxyhæmoglobin, while that of the baboon and some other animals contains as many as three, carries no conviction. Scepticism on this point appears, indeed, to be very much in place in view of the extraordinary statement in the last chapter that "metoxyhæmoglobin," the substance ordinarily known as methæmoglobin, the neutral or acid solutions of which show a four-banded spectrum, becomes converted to oxyhæmoglobin by treatment with ammonia. It is almost impossible to resist the conclusion that the authors are unfamiliar with the spectrum of alkaline-methæmoglobin, and the suspicion that the crystals described as a second kind of oxyhæmoglobin may have consisted of the former substance.

Another interesting statement concerning which ampler justification would have been very welcome is that the blood of the shad during the breeding-season, and that of the bear during hibernation, is especially rich in "metoxyhæmoglobin."

The first two chapters deal very completely with the general properties, and distribution in the animal kingdom, of hæmoglobin, hæmocyanin, and the colourless respiratory substances termed achroglobulins; they contain also some very useful comparisons of the chemical and morphological characters of the blood of different animals, and full references to the literature. The third chapter is devoted to a special consideration of the physical and chemical properties of hæmoglobin, and it is no fault of the authors that Barcroft's important work on this subject had not appeared in time for its inclusion. The rest of the monograph contains an admirable critical account of the work of previous investigators, and a full description of the methods, results, and conclusions of the authors, illustrated by 600 very successful photomicrographs and numerous figures in the text.

The results obtained are of general biological interest, not only as showing that the differences already proved to exist between the corresponding serum-proteins of different animals are equally manifest between their hæmoglobins, but also as throwing light on phylogenetic relations, since the crystals from closely allied species often exhibit close similarities. They are also of great interest to the crystallographer by reason of the extensive isomorphous series brought to light, and some important observations on mimetic twinning of crystals.

PROBLEMS OF WHEAT GROWING.

THE October number of *Science Progress* contains an important article on "Wheat-growing and its Present-day Problems," by Dr. E. J. Russell, of the Rothamsted Experimental Station. The article is based very largely upon a discussion which took place at the Winnipeg meeting of the British Association, at a joint meeting of the Botanical, Chemical, and Agricultural Sections. The work of the Rothamsted station has long ago made familiar the main facts in reference to the fertilisation of wheat-fields under normal conditions, but the recent discovery of the use of phosphatic manures in order to secure earlier ripening may prove to be an important factor in extending the northern limit of the wheat-belt; in the same way, it is suggested, the use of late-ripening varieties manured with potassium salts may be of value in extending the southern limit; phosphates have also proved of value in securing rapid root development in the dry soils of Australia, where it is of great importance that the plant should secure access to the subsoil water as quickly as possible. Reference is also made to the recent experiments of Dr. Saunders and others on the breeding of wheat in order to develop "strength," heavy cropping power, early maturity, and resistance to rust and drought. The work to be done here is very extensive, as different localities demand widely different types, owing both to economic and to physical differences. Even in a given locality the results obtained vary greatly according to the conditions, a "strong" wheat often giving a crop of weak piebald wheat when grown on newly broken land, whilst on old land the crop may be superior in quality to that used as seed, a difference that is perhaps due to the great decrease in the proportion of water in the older land during the period of growth of the crop. It is pointed out that continuous cropping with wheat appears to break down the fertility of the soil by bacterial changes, which result in disintegrating the nitrogen, rather than by chemical exhaustion; the soil recovers, however, when planted with clover and similar crops, which act as agents for the fixation of nitrogen; as this seems to fit in with the natural development of farming in a new country, the temporary loss of fertility is of less importance than might appear at first sight to be the case.

BOTANY AT THE BRITISH ASSOCIATION.

The President's Address.

IN accordance with the custom that is growing up of arranging for a minimum of clashing between the various presidential addresses, Prof. Trail delivered his address (which was printed in full in NATURE of October 6) at 12 noon on Thursday, September 1. The address dealt with the subject of field botany, and the president particularly urged the need for the preparation of a really great national flora. As a direct outcome of the address, a committee was subsequently appointed, with Dr. Trail as chairman, to consider what steps should be taken towards organising and preparing the materials for such a flora.

As regards the rest of the proceedings, the outstanding features of the Sheffield meeting were the sittings devoted respectively to physiology, cytology, and morphology. Judged by the keenness of the discussions and the numbers attending the section, the meeting must be pronounced to have been distinctly better than the average. It will be convenient to deal first with the subject of physiology.

Physiology.

On Monday morning, September 5, there was a joint sitting of the botanists, chemists, and physiologists in the meeting-room of Section K, the subject being the biochemistry of respiration. A report of this discussion will be found in the account of the proceedings of Section I (p. 26), so it is unnecessary here to do more than mention the botanical contributions to the discussion. Dr. F. F. Blackman, who opened the subject, by way of introduction outlined our present knowledge of the respiration of plants in respect to:—(1) the nature of the reaction (or reactions) which constitutes respiration; (2) the physical chemistry of the respiration reaction; and (3) the influence of protoplasm upon the progress of the reaction. Mr. D. Thoday dealt with the effect of chloroform on the respiration of plants.

Tuesday morning, and to some extent Wednesday, were also devoted to physiological papers. Mr. S. Mangham read an interesting paper on the paths of translocation of sugars from green leaves. Using Senft's method of testing for sugars by the precipitation of osazones, the author was able to obtain definite evidence that the sieve-tubes (and not the parenchymatous vein sheaths) provide the main paths for the translocation of free sugars from the lamina of the leaf. He was thus able to confirm Czapek's theory, which had been disputed by Haberlandt and others. Mr. D. Thoday followed, and discussed assimilation and translocation under natural conditions. His experiments show that in detached leaves the increase of dry weight, due to assimilation, is surprisingly small in bright diffuse light as compared with bright sunlight. Leaves still attached to the plant show a smaller rate of increase than detached leaves; this is probably largely due to translocation. Dr. F. Darwin demonstrated a new method of observing in living leaves, while still attached to the plant, the degree to which the stomatal apertures are open or closed. The instrument (which he calls a *porometer*) consists of a small glass chamber cemented on to the stomatal surface of a leaf, and connected with a suction tube and manometer. By diminishing the air-pressure in the chamber a flow of air through the stomata is induced, the rate of flow indicating the condition of the stomatal apertures. Dr. Darwin then discussed some actual results obtained by the porometer. On comparing the readings of the latter with the loss of weight by transpiration, it was found that the two curves rise and fall together, but the transpiration readings have a much smaller range than those of the porometer. This is perhaps what might have been expected, taking into account Dr. Horace Brown's work on diffusion.

Miss N. Darwin and Dr. F. F. Blackman contributed a paper on germination conditions and the vitality of seeds. If the vitality of seeds is lowered by exposure to, *e.g.*, high temperatures, they do not germinate well, and become more sensitive to any unfavourable modification of the environment. Failure to germinate when too little water is present is due to purely physical causes, while the injurious effects of excess of water are due to the water acting as an oxygen excluder. Mr. A. S. Horne next discussed the absorption of water by various leguminous seeds. Prof. Bottomley showed that the Cyanophyceæ endophytic in the apogeotropic roots of cycads and in the cavities of Azolla and Anthoceros are invariably accompanied by nitrogen-fixing bacteria. He suggested that this may really be a symbiotic association of the algæ and the bacteria.

Ecology.

In contrast to the Winnipeg meeting, ecology was represented this year by only two papers. Mr. J. H. Priestley gave an account of the distribution of halophytes on the Severn shore. In this district the halophytes exhibit three well-marked zones:—(1) the low-lying Salicornia zone; (2) the Sclerochloa and Aster zone; and (3) the rarely submerged *Juncus Gerardi* and *Festuca rubra* zone. Apparent anomalies of distribution are probably referable to differences of drainage and salinity. Mr. M. Wilson discussed plant distribution in the woods of north-east Kent.

Cytological Papers, &c.

Friday morning was occupied with papers dealing with cytology and heredity, the first two being taken jointly with Section D (Zoology). In a paper entitled "The New Force, Mitokinetism," Prof. Marcus Hartog further developed his views on the formation of the spindle and other structures observed during karyokinesis. Discussing the various theories put forward, Prof. Hartog contended that neither diffusion currents on one hand, nor electrolytic or electrostatic force or magnetism on the other, are sufficient to account for the formation of the mitotic spindle. As an alternative the author postulates the existence of a new force, which he terms "mitokinetism," and which, so far, is unknown outside the living cell. Dr. E. Hindle followed with an account of artificial parthenogenesis in the eggs of a sea-urchin (*Strongylocentrotus purpuratus*). The author described the process of artificial fertilisation in these eggs by treatment with a monobasic fatty acid, and subsequently with hypertonic salt solution. The cytological changes undergone were carefully described, including the formation of an artificial fertilisation membrane and the various nuclear changes. Under suitable conditions free-swimming larvæ were produced. These, though their dividing nuclei contained only the reduced number of chromosomes, were identical in form and behaviour with those developed from normally fertilised eggs. This concluded the joint sitting of Sections D and K, and the remaining papers were communicated to Section K alone.

The next two papers dealt with the behaviour of the chromosomes during mitosis, and particularly with respect to the stage at which longitudinal fission is initiated. Prof. Farmer and Miss Digby found in Galtonia that during the archesporial divisions the longitudinal fission begins by a condensation of the chromatin on the edges of the chromosomes during the telophase of the preceding division, and the duplicate character can thus be detected very early. Similarly, in the heterotype division of mitosis, the longitudinal fission is prepared for, as in the somatic mitoses, during the telophase of the last archesporial division. Dr. Fraser and Mr. Snell obtained very similar results in *Vicia faba*. They found that the chromosomes which are separated from each other in any given division are the product of a longitudinal fission which is initiated in the preceding telophase. This was stated to be the case in both the sporophyte and gametophyte generations, the resting chromosomes in both cases exhibiting a double structure. Prof. V. H. Blackman, in a very interesting short paper, described the vermiform male nuclei of Lilium. The author brought forward evidence that, although purely nuclear in structure and possessing no cilia, these structures are capable of active movement. It seems probable that the activity of these nuclei, and not the streaming movements of the surrounding cytoplasm, is responsible for their entrance into the ovum and passage to the polar nuclei.

The remaining two papers taken on Friday dealt with problems of heredity. Mr. R. P. Gregory offered some further observations on inheritance in *Primula sinensis.*

and Prof. F. E. Weiss described some experiments on the inheritance of colour in the pimpernel. The latter author crossed *Anagallis arvensis* and *A. coerulea* (the red and blue pimpernels). The red colour proved to be dominant, while in the f_2 generation there was complete segregation into red and blue forms. This is another interesting case of a recessive blue in the Primulaceæ.

Fungi.

The fungal papers were taken on Thursday morning before the president's address. Prof. Buller discussed the function and fate of the cystidia of Coprinus. The author confirmed Brefeld's view that the cystidia act as props to keep the gills from touching each other. He pointed out that this is necessary to allow for the free escape of the ripe spores. The cystidia themselves disappear by a process of autodigestion just before the basidia in their immediate neighbourhood are ready to discharge their spores. In the discussion on this paper Mr. Wager suggested that the cystidium must be regarded as having been phylogenetically derived from the basidium. Mr. A. E. Lechmere read an interesting paper on the methods of asexual reproduction in a species of Saprolegnia. In hanging-drop cultures great variation was found in the behaviour of the zoospores, the method of discharge, and the shape of the sporocyst. Variations of form, &c., supposed to be characteristic of distinct genera of the Saprolegnieæ were found within the limits of this single species. Prof. V. H. Blackman described a form of nuclear division intermediate between mitosis and amitosis in *Coleosporium Tussilaginis*. A spindle is formed on which granular chromatin collects, and is then drawn apart towards the poles. The chromatin is not aggregated into definite chromosomes. Mr. Harold Wager, in a paper on chromosome reduction in the Hymenomycetes, maintained that normally only two nuclei (each containing four chromosomes) fuse in the basidium. During the division of the fusion nucleus the spireme breaks up into eight chromosomes, reduction being brought about in a simple manner by the distribution of the chromosomes to the two daughter nuclei. Mr. F. T. Brooks described his investigations into the cause of the silver-leaf disease of fruit trees. These experiments are still proceeding, but, although not absolutely proved, the available evidence points, as previously suggested by Percival and Pickering, to *Stereum purpureum* as the probable cause of the disease.

Morphological and other Papers.

Although only an afternoon session (on Monday) was available for morphology, the papers proved so attractive that the section sat for nearly three and a half hours. Prof. F. O. Bower led off with two papers. The first was a short note on *Ophioglossum palmatum*. The divided character of the leaf-trace supports the conclusion, previously arrived at from its external morphology, that *O. palmatum* is one of the more extreme and specialised types of the Ophioglossaceæ. The second paper, on two synthetic genera of Filicales, dealt with some very interesting problems of phylogeny. The two genera in question are Plagiogyria (formerly included in Lomaria) and Lophosoria (usually grouped with Alsophila). The author not only put forward strong reasons why these respective genera should be kept separate, but suggested that both are probably important intermediate synthetic forms. Thus he regards Plagiogyria as a transitional form related on the one hand to the Gleicheniaceæ and the Schizæaceæ, and on the other to the whole series of Pterideæ. Similarly in the case of Lophosoria, a probable sequence may be traced from forms also having affinities with the Gleicheniaceæ through Lophosoria to Alsophila and other Cyatheaceæ.

Dr. Kidston and Prof. Gwynne-Vaughan described the structure of the "false stems" of the fossil genus Tempskya. This plant had an extraordinary habit. Its erect "stem," which grew to a height of 9 or more feet, really consisted of an aggregate of branching stems embedded in a compact mass of their own adventitious roots. The individual stems were slender, and possessed a dorsi-ventral symmetry. The authors think that in this case the erect habit had been only recently acquired, the particular method adopted being one which could be evolved with great rapidity. They further suggest that the erect habit of modern tree-ferns may be a secondary character derived from Tempskya-like forms, in which the original axis has developed at the expense of the lateral branches. Dr. M. C. Stopes read a paper in which she further described the fossil flower *Cretovarium japonicum*, dealing especially with the structure of the ovary. Mrs. Thoday, in a communication on the morphology of the ovule of *Gnetum africanum*, instituted a comparison between this and the ovules of Welwitschia and Lagenostoma. She regards the ovule of Gnetum as probably more primitive than that of Welwitschia on account of its radial structure, the presence in the young ovule of a well-developed pollen chamber, and the small development of the free portion of the nucellus. Prof. F. W. Oliver next discussed the pollen chambers of various fossil seeds. He showed that in certain seeds (*e.g.* Conostoma spp.) the structure of the nucellar apex is much more complex than in forms such as Lagenostoma, &c. In these more complicated forms a second pollen chamber was excavated below the primary one (which alone is found in Lagenostoma), the latter becoming merely vestigial. In the light of this discovery it seems possible that the nucellar beak of Trigonocarpus, Ginkgo, &c., may represent a vestigial primary pollen chamber, which had been functionally replaced by a more deeply seated cavity.

Prof. W. H. Lang concluded the afternoon's sitting with a very interesting account of the morphology of the stock of Isoetes. He produced evidence that the stock grows regularly in two opposite directions. Leaves are produced at the upper end, the stem apex being situated at the base of a deep depression. Similarly, the roots are borne in regular sequence on a downwardly growing region. In this case, too, the apex is at the bottom of a deep depression, but the growing point is obscured by the congenital union of the sides of the depression. The young roots are finally freed by the gradual and partial separation of the united lobes of the stock. Although greatly modified, the axis of Isoetes is strictly comparable with that of Lepidodendron or Pleuromeia.

The Semi-popular Lecture

this year was given by Prof. F. O. Bower, the subject being "Sand-dunes and Golf Links." The lecture, which was greatly appreciated, dealt chiefly with the part played by vegetation in the formation and fixing of sand-dunes. Perhaps the prominence given to this part of the subject caused some mild disappointment to the golfers present, who wished for practical hints on the keeping of greens. Prof. Bower showed a number of beautiful photographs, amongst the most interesting being some of shifting dunes.

ENGINEERING AND CIVILISATION.[1]

IN order rightly to appreciate the share taken by our profession in bringing about the present state of civilisation, a comparison should be made between the conditions prevailing, say, in the Greek states during the fifth and fourth centuries before Christ and those existing now in the twentieth century after Christ.

In indicating the state of knowledge at that period of Greek history, it is enough to remind you that it was the age of Themistocles, Aristides, and Pericles, the statesmen; of Æschylus, Sophocles, Euripides, and Aristophanes, the dramatists; of Phidias, Scopas, and Praxiteles, the sculptors; of Apollodorus, Zeuxis, and Apelles, the painters; of Ictinus, the chief designer of the Parthenon, and Dinocrates, who rebuilt the temple of Diana at Ephesus and laid out the city of Alexandria, the architects; of Herodotus, Thucydides, and Xenophon, the historians; of Socrates, Plato, and Aristotle, the philosophers.

Can we say that there have been many since that time who are worthy to be mentioned as equals of the men I have just named? The fact alone that we use the adjective "classical" to indicate perfection in literature and art shows what a standing had been attained more than 2000 years ago, and in many respects we feel down

[1] From the Presidential Address delivered at the Institution of Civil Engineers on November 1, by Mr. Alexander Siemens.

to the present time the direct influence of Greek and Roman learning.

In his "Organon" Aristotle expounded the logic of deductive reasoning in such a complete form that even the terms which he was the first to establish are in use at the present time, and both Kant and Hegel acknowledged that from the time of Aristotle logic had made no progress. But the schoolmen did not realise that the "Organon" was merely an "instrument" setting out the theory of reasoning; they neglected altogether the teaching of Aristotle, that in every branch of science or art the only means of obtaining premises on which logical deductions can be based is by experience and observation of facts. He says in the "Prior Analytics," I., xxx., 3:—"When the facts in each branch are brought together it will be the province of the logician to set out the demonstrations in a manner clear and fit for use."

This principle of bringing together facts was absolutely neglected in mediæval times by the later schoolmen, even when, during the thirteenth century, the complete works of Aristotle, translated into Latin, had become known to them, although at first the Church authorities would not allow any lectures to be delivered on them in the universities.

A reaction against Scholasticism, or Obscurantism as it is sometimes called, set in during the fifteenth century; it was strongly supported by the Reformation, but it is the merit of Sir Francis Bacon to have directed the course of the further studies of mankind into the right channel by showing that the object of all science is to recover man's sovereignty over nature, or, as he expresses it, "to extend more widely the limits of the power and of the greatness of man" ("Novum Organum," I., 116).

For this purpose, Bacon asserts, it is necessary to study nature by inductive investigation after observing and collecting facts, but, in contrast to the deductive reasoning adopted by the schoolmen, he lays down that "the induction that is to be available for the discovery and demonstration of sciences and arts must analyse nature by proper rejections and exclusions, and then, after a sufficient number of negatives, come to a conclusion on the affirmative instances, which has not yet been done save only by Plato . . . and this induction must be used not only to discover axioms, but also in the formation of notions" ("Novum Organum," I., 105).

Although it cannot be said that the Baconian method has been followed in its entirety during the subsequent development of science, its fundamental ideas, viz. the need for rejecting rash generalisation and the necessity for critical analysis of experience, serve as the sound basis of the modern method of framing hypotheses and verifying them by observation and experiment.

In literature and art or in philosophy we cannot boast of being greatly superior to the ancients, but, so far as engineering problems are concerned, we have enormously advanced, thanks to the practical application of scientific theories.

Comparing generally the conditions of life then and now, we may sum up the difference by claiming that our progress is due principally:—(1) to the improvement of the means of communication; (2) to the saving of manual labour by the introduction of mechanical power; which main features have caused a general lowering of the cost of "obtainables."

When Hertz discovered the property of electric sparks to start waves of the æther which can be detected at a distance, nobody anticipated that Marconi and others would succeed in developing these small beginnings to the system of wireless telegraphy, of which nowadays so many applications are in constant use.

Again, the polyphase motors and generators of electricity had their beginning in the researches of Prof. Ferraris, who demonstrated that three alternate currents can be combined in such a manner that the sum of the three currents at any moment is equal to zero, and that by their aid a revolving magnetic field is produced.

When we seek to recognise true progress in the material conditions under which we are living, it is not unreasonable to expect that any further advance will be made on the same lines as differentiate our present civilisation from that of the ancients, and that "lowering the cost of obtainables," based upon improvement of communications and upon the saving of manual labour, will furnish a trustworthy test whether a change suggested to be made in our material surroundings is worth adopting or is merely an alternative without any prospect of being generally accepted.

The development of the manufacture of glow-lamps is a striking example of the advantage of labour-saving machinery; at first the lamps were made by a few skilled workers at a high cost, so that they could not be sold for less than twenty-five shillings each. This excessive cost naturally restricted their sale; but the efforts of the manufacturers to devise labour-saving machinery were not relaxed until the selling price of glow-lamps had diminished to its present level, when they are sold by the million. Can anybody doubt that the introduction of labour-saving machinery into this industry, far from diminishing opportunities for employment, has not only benefited the skilled workers, but has opened new avenues for profitable employment to the so-called unskilled labour.

Nor is the advantage limited to this particular industry; the possibility of obtaining cheap glow-lamps has increased the sale of dynamos, steam and gas engines, cables and fittings, giving employment to thousands of workmen. Similar consequences have followed the introduction of labour-saving machinery into other branches of manufacture.

In their own interest inventors should appreciate more than they have done in the past that progress is not the result of flashes of genius that illuminate suddenly a hitherto unknown subject, but that it can only be gained by plodding work and careful study directed by an infinite capacity for taking pains.

This requirement is expressed very tersely by Aristotle in his definitions of science and of art, which, unfortunately, have been lost sight of in the course of ages, so that they cannot be used any longer. They are, however, so appropriate to our subject that I do not hesitate to repeat them.

Aristotle says:—Science is the trained faculty of demonstrating necessary conclusions from necessary premises, and these conclusions are independent of the producer.

Art is the trained faculty of producing, involving sound reasoning; it has to do with the genesis, the production of things, and the result depends on the producer.

From these definitions it follows that every profession requires to have its "science" which teaches the "sound reasoning" on which its "art" is based, and for both "science" and "art" training is a necessary condition for success.

They indicate, to my mind, for our profession in particular, that the college teaching should occupy itself principally, though not exclusively, with "science," viz. the natural laws which are "independent of the producer," leaving the "art" of engineering to be developed by practical work either in the field, in the drawing office, or in the workshop.

So far as the "science" of any industry is concerned, all civilised countries have access to the results of the latest researches which are published without loss of time in the technical journals, and the "art" of each industry devotes itself everywhere to the problem of lowering the cost of production in order to widen the circle of possible customers.

Viewing the question of international competition from this aspect, it can only be regarded as an extension of the competition at home, and, applying the same reasoning, the question naturally arises whether it would be desirable to have international standards or not. Looked at from the point of view of the consumer, it certainly appears to be very convenient to be able to obtain supplies from a number of different sources with the certainty of their being interchangeable, or at least equivalent.

In fact, the same reasons that have led to the establishment of the Engineering Standards Committee in this country hold good for international dealings, so that we may look forward to the time when international standard specifications will be accepted all over the world. A beginning was made when the British Association introduced in 1861 the C.G.S. system of electrical units, which, since that time, have been adopted internationally, and a further step was taken at the St. Louis Exhibition of

1904, when the International Electro-technical Commission was called into being.

It is a very significant circumstance that it has been found necessary for this commission to associate itself in some branches of its activity with the Engineering Standards Committee, and it is not unreasonable to expect that such joint international action will gradually extend beyond the field of electricity.

FORESTRY EDUCATION: ITS IMPORTANCE AND REQUIREMENTS.[1]

I PROPOSE to deal to-day with a brief exposition of the points on which the system of forestry education is based. It will be of interest, I think, first to glance briefly at the training to be obtained at some of the European forestry schools, and the facilities provided for giving it. We will then consider some of the things the student in forestry must know, and in this connection glance briefly at a few of the duties which confront the forest officer in the course of his ordinary work in India, concluding, finally, with a review of the present position of the university as regards forestry training and the steps which require to be taken to enable us to send out the class of British forester which is already required in many of our colonies, and for which we trust there will soon be a demand in the British Isles.

A few years ago, whilst on furlough from India, I made a tour of some of the forestry colleges and schools of Europe, my object being to study the lines upon which the Continental system of education was based and the methods they adopted to combine a proper proportion of practical work with the theoretical instruction given in the class-room. In the course of my tour I visited Eberswalde, Tharandt, Aschaffenburg, and Munich Forestry Schools in Germany, the Imperial Forestry Institute at St. Petersburg, the Agricultural and Forestry Institute at Vienna, and the fine French Forest School at Nancy. That tour was an education in itself. Briefly, I may sum up the results of my observations as to the essentials for the tuition of forestry thus:—(1) a strong teaching staff; (2) good museums; (3) a forest garden and forest educational woods.

(1) *The Instructional Staff.*—The study of forestry so depends on a number of cognate subjects, such as botany, chemistry, geology, zoology, surveying, and forest engineering, &c., that it is essential that the student should be given first-class courses in these matters. Excellent courses are given in all the Continental colleges. There remains the subject of forestry itself, comprising the various branches of silviculture, forest management, forest valuation, forest protection, forest utilisation, the law of the forests, and procedure and accounts. To lecture on these various branches, the best Continental colleges retain the services of at least three men, professors and assistants, many of the former having world-wide reputations in their various branches. These men are also often responsible for their own departments of work in the school forest garden and instructional forests. Their work, as we shall see, falls under two heads. They deliver courses of lectures in the lecture hall, and they conduct the students on the excursions made into the woods to illustrate these lectures, and personally supervise every piece of practical work laid down for the student to do. Since the minimum time in which a student can finish the forestry course is two years, the professor requires at least one assistant to conduct a part of the lectures, for the junior and senior students are both necessarily attending courses at the same time, and one lot may be in the woods whilst the other is in the lecture hall. At the well-known Forestry School at Munich, the home of a number of famous foresters, the various branches of forestry science are in charge of three professors: Prof. Mayer takes silviculture, forest utilisation, protection, and foreign forestry; Prof. Endres, forest policy, administration, valuation, and finance; whilst Prof. Schüffer lectures in forest management and working plans, estimation of increment, and yield. Each of the professors is responsible for the excursions, laboratory and practical work, of their various courses.

(2) *Good Museums.*—The educational value of a good museum is fully recognised. It need not be enlarged upon here. Forestry is peculiarly a science the tuition of which on the one side and assimilation on the other is dependent upon two essentials, a thoroughly efficient system of practical work, and up-to-date, well-planned museums exhibiting in a simple and efficient manner the various details connected with forest work.

So important is the museum as an adjunct to the efficient teaching of forestry that we find in all the Continental forestry colleges that considerable sums of money have been spent on this part of the equipment alone, and yet in some instances, although with treble the space available here in Edinburgh, the cry was often that more room was required. Where all is so good it is difficult to particularise, but as examples of efficiency in this respect I will instance the museums at the Forestry School of Nancy in France, the Imperial Forestry Institute in St. Petersburg, and the Forestry College at the University of Munich. The latter, so far as its building accommodation and museums are concerned, forms the nearest parallel to the position of Edinburgh University, and it will be of interest to glance briefly at the accommodation provided.

The Forestry College at Munich forms part of the University of the town and State, and considerable sums of money were spent a few years ago with the object of bringing it thoroughly up-to-date. The buildings devoted to forestry instruction are two in number, both situated in the grounds of the University.

The new building, which was opened about the year 1900, is the most perfect institution of its kind that man could have devised. The whole of the inside fittings are of wood, highly polished parquet flooring being used throughout, whilst the rooms are handsomely panelled with various kinds of woods. The chemical, mineralogical, meteorological laboratories, &c., are in the basement; forest surveying, mathematics, and forest-wood museums on the first floor; and forest implements, forest products, and models and diseases of woods on the next floor. Each of these branches or departments of science has its own museums, one or two rooms as are required, its own large lecture hall, with professors' and assistants' rooms, laboratories where required, packer's room, &c.

The space devoted to forestry pure and simple is ample, no fewer than five large rooms and halls being devoted to the exhibition of the collections alone, those of each branch being exhibited alone.

This brief description will show that there is little fault to be found with the arrangements and space devoted to this wonderfully efficient forestry college. With such equipment there is every incentive to professor and student alike, not only to work, but to undertake research work in the various branches of forestry. In the Bavarian University the State pays for the upkeep of the major portion of the Forestry Department, and in return the Government reaps the advantages derived from the very important research work and experimental work in which its professors, many with great European reputations, spend all their spare time.

(3) *The Forest Garden and Educational Woods.*—We come now to our third essential to the proper teaching of forestry, the forest garden and educational woods. It may be said at once that the subject of forestry cannot be taught by the professor or assimilated by the student unless efficient instructional woods are available to which the student can be taken during the lecture course, as well as during the practical course, to be shown eye object-lessons of what he is told. He should be shown in the woods what he is told in the lecture-room, and taught to observe for himself—that first and most important of the lessons of a forester. These first principles of the education of a forestry student are well understood on the Continent, and are adequately provided for.

I will give two instances out of many. The German Forestry Academy of Tharandt is situated not far from Dresden, in Saxony. The school is provided with a forest garden and demonstration forest, forming a compact block in its immediate vicinity. The forest garden is situated on a hill-side immediately behind the school. The hill-

[1] From the inaugural lecture delivered at the University of Edinburgh on October 12, by Mr. E. P. Stebbing, Head of the Forestry Department of the University.

side is terraced into beds, which contain some 1800 different species of trees, shrubs, perennials, and annuals of various kinds, both indigenous and exotic. This garden serves as a forestry and botanical garden, and is an exceptionally fine one, covering an area of about 18 hectares. There is a forest nursery in the garden managed on most up-to-date lines.

The school demonstration forests adjoin the forest garden, and are kept up entirely for educational and demonstration purposes. They are situated in a hilly area presenting ever-varying conditions, aspects, and variations in soil, thus allowing of a variety of object-lessons with different species and mixtures being presented to the student. For example, these woods contain spruce and beech with birch in mixture; spruce and silver fir, or the two latter with birch. Or again, there are woods of spruce, beech, Scotch pine, silver fir, larch, maple, birch with maple and various mixtures, ash (pure, about thirty years old), alder (in wet valleys), oak, and a little Æsculus. There are some most interesting mixtures to be seen doing remarkably well, and forming an ideal of what demonstration woods should be. The steep slopes of the hill-sides are worked under different sylvicultural systems to the area of tableland above, where the woods are clear-cut and naturally regenerated or sown or planted. Exotics are being largely introduced, and thousands of plants are sent out annually from the forest garden and nursery in the demonstration area into the forests all over Saxony. Fencing of young planted areas and other ways of protecting young plants from deer, &c., are to be seen in practice in the woods. Time will not permit of my dwelling upon this excellent educational demonstration area; but from his earliest course in the lecture-room the student is taken out week by week into the forest garden or woods, and with his own hands learns how to trench, sow, plant, thin, and fell and measure up his woods; is taught to distinguish the different species of tree, and how they differ in their requirements of soil, light, moisture, &c.; is shown on what the foundations of sylviculture depend; and is gradually led, step by step and stage by stage, to understand and grasp both the theory and practice of the various branches of the lore of the woods comprised in forestry.

I should like to give another instance of this educational forest. The Imperial Institute of Forestry at St. Petersburg is probably the largest forestry college in Europe. The students number 500, all training for the controlling staff. In addition, there are thirty-three lower-grade schools containing fifteen students apiece, from which the ranks of the forest rangers and upper guards are filled. Attached to the institute at St. Petersburg are two educational forests, the one 14 versts (9 miles) from the capital, the other, and larger, 60 versts (40 miles) away. At each of them buildings are maintained for housing the professors and students during their visits. Portions of every summer are spent by the students in these woods occupied in practical work. The woods are entirely under the management of the director of the college, as is the case at Tharandt, and are managed on similar lines, and solely for demonstration purposes. The directors at both these places, as also the forestry professors (and this applies to many of the Continental colleges), are all practical men who have themselves been through the mill of executive work, have themselves held charge of large areas of woods worked entirely on a commercial basis, and are therefore in a position to see that the instruction given to the students is such as will return full value to the State or proprietor who employs the men leaving their institutions.

This is a point which I think worthy of the most serious consideration in this country. Too great stress cannot be laid on what are, after all, actual facts. The excellent and remunerative results of forestry in Europe, which we also wish to arrive at in the British Isles, are solely the result of the study of higher forestry both in the woods and in the laboratory. Practical foresters can only be successful in proportion to the knowledge they themselves possess or which is imparted to them by those who know. We can learn from other countries a great deal, but the application of what we learn must depend on ourselves and must be carried out by ourselves.

We have now seen what the Continental forestry colleges consider the essentials to the proper tuition of forestry as a science, and have shown how the student is gradually led, not only to assimilate the theoretical portions of the study in the lecture-room, but to take with him what he has absorbed there and apply it practically in the woods. We have seen that these practical object-lessons must begin with the student's first lectures, that he must be taken into the woods at the beginning and be shown, step by step, that what he is being told in the lecture-room is not so much matter to be studied for an examination and to be subsequently forgotten when his text-books and note-books are thrown aside after the "pass" has been gained. It has been said of the forester that he is always at school, from the moment he first enters the lecture-room to commence his first course to the end of his life; and those of us who are foresters know this to be true. Our text-books and lecture notes remain our trusted friends to the end, and as we grow older and have had a more extensive practice and experience in forestry we grow more diffident about expressing definite opinions and laying down the law on the subject of the life-histories of our friends the trees. For the tree is very much like the human being. He has his wants and requirements, his fancies for particular aspects and localities, for certain soils and degrees of light, moisture, heat, and shade.

All these the forester must know and study, and even then his fastidious friend will often discover something he dislikes, and refuses to grow. The forester has to set to work to find out what this something is, and meanwhile all he has done is a failure—a failure, that is, unless he is a thoroughly trained scientific man. As such he will turn his failures to account, for he will place them on record so that he and others like him may set to work to get at the reasons for the failure of a crop which, so far as human forethought was capable of doing, had been given every chance. How much sound practical knowledge and observations have been lost to the foresters all over the world by this regrettable neglect to place upon record their failures. Almost more valuable are they to record than the successes; to the forester far more valuable. This is one of the spots upon which the scientific forester can place a finger in the British Isles. Had one a full, or even a partial, record of all the failures of the past, how much simpler would be the task at present facing the nation of getting its forestry house in order.

Scotland is more favourably situated and in a better position as regards woods of a high educational value than any other portion of the British Isles for undertaking this necessary research work. There are woods in Scotland, many of them known by repute, others less well known, in which the student on his practical course can learn a great deal and in which work of high importance to afforestation in the British Isles can be carried on. Edinburgh is very favourably situated for participating in this pioneer work, and has every intention of taking her share in it.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—To-day, November 10, Graces will be offered to the Senate proposing that the offer of the Worshipful Company of Drapers to erect a new physiological laboratory at Cambridge be gratefully accepted, subject to the conditions set forth in the letter, dated February 11, 1910, from the clerk to the company; that a syndicate be appointed to discuss details with the company; and that the Vice-Chancellor be authorised to convey to the court of assistants of the company the grateful thanks of the university for their munificent benefaction. Further, that the Vice-Chancellor, Dr. Mason, Master of Pembroke College; Mr. Shipley, Master of Christ's College; Dr. Langley, professor of physiology; Dr. W. M. Fletcher, and K. Lucas, of Trinity College, be the syndicate appointed under the above-mentioned Grace.

Applications for the tenure of the Benn W. Levy studentship in bio-chemistry should be sent to Mr. F. G. Hopkins, Trinity College, on or before Wednesday, November 30, 1910. Applicants should state their university standing and previous scientific experience, mentioning if they are in receipt of any other endowment for research. The studentship is open to members of the University of Cambridge who have been admitted to a degree, or to members of

Girton or Newnham Colleges who have acquitted themselves so as to have deserved honours and have fulfilled the conditions respecting length of residence which members of the university are required to fulfil before being admitted to a degree. The annual value of the studentship is 100*l*. The student, during his or her tenure of the studentship, shall prosecute original research in bio-chemistry, and shall not engage in such other work as in the opinion of those entrusted with the administration of the fund would seriously interfere with his or her original inquiries. The appointment will be for one or two years, at the option of the managers.

Notice is given that a prize of 50*l*. out of the Gordon-Wigan fund will be awarded at the end of the Easter term, 1911, for a research in chemistry, of sufficient merit, carried out in the University of Cambridge. Candidates for the prize must have taken Part I. of a Tripos examination, and be under the standing of M.A. The research may be in any branch of chemistry. The dissertation, with the details of the research, must be sent to the professor of chemistry not later than June 10, 1911.

The local examinations and lectures syndicate is about to appoint an assistant secretary for examinations. The person appointed will be expected to enter on his duties not later than January 1, 1911. The appointment will be made in the first instance for the period ending March 31, 1912, at a stipend of 400*l*. a year. The post will after that date be held during the pleasure of the syndicate, and the stipend will be raised by annual increments of 25*l*. to 500*l*. Graduates of the university who desire to offer themselves as candidates are requested to send their names to Dr. Keynes, Syndicate Buildings, so as to reach him not later than 9 a.m. on Monday, November 21.

The Vice-Chancellor gives notice, on behalf of the Board of Geographical Studies, that Mr. R. T. Günther has consented to deliver a lecture in Cambridge on Friday, November 11, at 5 p.m., on "Earth Movements of the Italian Coast." The lecture will be given in the Sedgwick Museum, and will be illustrated by lantern slides. Members of the University and others are invited.

The Regius professor of physic gives notice that Prof. Osler has consented to deliver a lecture on November 17, at 5 p.m., in the large theatre of the medical schools, on "Medical Education in France."

OXFORD.—The congregation of the University of Oxford had before it on November 8 the first of the important series of statutes framed by the Hebdomadal Council, in pursuance of the comprehensive scheme of reform initiated by the Chancellor, Viscount Curzon. The adoption of the statute, which deals with the constitution and powers of the boards of faculties, including that of mathematics and natural science, was advocated by the President of Magdalen, the Master of University College, and Prof. Geldart. Its provisions were sharply criticised by the Warden of All Souls and the Master of Balliol, and its rejection was recommended by Prof. Holland and the President of Corpus. The preamble was carried in a full house by a majority of rather more than two to one; but there is no doubt that strong efforts will be made to modify the effects of the statute by amendment, especially those of its provisions which deal with the composition of the electorate and with the control exercised by the University and colleges respectively over the subjects and methods of instruction.

The tenancy of the well-known house in Broad Street, long the residence of Sir Henry Acland, has lately been acquired for the Oxford School of Geography. When the necessary arrangements have been completed, the house will contain a library, reading-room, and collections of maps, views, and models. Part of the premises will be fitted up for the use of the Beit lecturer in colonial history (Mr. W. L. Grant), and accommodation will be provided for purposes of general geographical instruction and research. The whole will be under the direction of Prof. A. J. Herbertson. This much-needed development of the facilities for geographical studies in the University has been made possible by the generosity of Mr. Bailey, of Johannesburg, who has given 500*l*. towards the adaptation of the house, and has promised 250*l*. a year for five years towards its maintenance.

Mr. O. G. S. Crawford, of Keble College, has been appointed junior demonstrator in geography for one year.

Mr. G. C. Robson, formerly exhibitioner of New College, has been elected to the vacant Naples biological scholarship lately held by Mr. J. S. Huxley, of Balliol College.

Mr. Selwyn Image, of New College, who has recently delivered his inaugural lecture as Slade professor of fine art, is a well-known student of the microlepidoptera, and is at present a member of the council of the Entomological Society of London. The seal of the society, which is a work of great artistic merit, was designed by the new Slade professor.

To encourage further interest in the subject of oceanography, it has been decided to invite the members of Dr. Bruce's class in geography at the summer school at St. Andrews this year to write essays on certain aspects of oceanography, and to submit them at the end of next spring. The essays are to be on one or other of the following subjects:—(*a*) on the effects of wind, temperature, and salinity on the circulation of the ocean, or (*b*) on the question of continental connections. The competition is only open to members of Dr. Bruce's class, and the essays must be lodged with the director of studies on the last day of April, 1911. Two prizes will be awarded, viz. two sets of the report on "The Scientific Result of the Voyage of the s.y. *Scotia* during the Years 1902, 1903, 1904." The two successful essays will be published either by the Scottish Oceanographical Laboratory or in the *Scottish Geographical Magazine*.

THE *Electrical Review* in its issue of October 21 directs attention to the great falling off in attendance at the evening classes of our technical schools which occurs during the course of each winter session. It contrasts the eagerness of the prospective student in consulting the teachers as to his course, in buying the text-books, and in making all his arrangements for strenuous work during the forthcoming winter evenings, with his tired and weary look and his vain attempt to follow the explanations given by his class teacher three months later. For this change, sheer fatigue and inability to stand the strain of perpetual day and evening work are responsible, and the *Review* charges the evening-school authorities with attempting too much and demanding attendance on the part of students for four or five evenings per week. It points out that undue strain can only be prevented by a reduction of the evenings of attendance to two, or in exceptional cases to three, per week, and urges the authorities to take this step as a means of improving both day and evening work of the students who attend their evening classes.

THE DUKE OF CONNAUGHT on November 5 laid the foundation-stone of the new University Hall of the Cape University. The council of the University presented an address, in which the hope was expressed that the union now accomplished in South Africa would lead to the conversion of the present Cape University into a teaching university for the whole of South Africa, by incorporating existing institutions of higher education as constituent colleges, and by creating chairs for those subjects for which no single college could provide. In replying, the Duke of Connaught said he trusted that the funds necessary to convert the Cape University into a great teaching university would be forthcoming. At a university luncheon held on the same day, Mr. Malan, Union Minister of Education, announced that Mr. Otto Beit had agreed to divert the sum of 200,000*l*., bequeathed by the late Mr. Alfred Beit for the foundation of a university at Johannesburg, to the creation of a great teaching university at Groote Schuur, the estate of the late Mr. Cecil Rhodes outside Cape Town. It was also announced that Sir Julius Wernher has promised to make up the amount to a total of 500,000*l*.

A NEW engineering laboratory was opened at the Darlington Technical College on October 20 by the Hon. C. A. Parsons, F.R.S. During the course of his address Mr. Parsons said that in the early part of last century engineering was principally guided by traditional rule and trade knowledge, handed down from father to son and from master to apprentice. Engineering has gradually assumed a more important place, its field of operations has become wider and more complex, and it has become

imperative to institute, instead of the old and primitive methods, systematic technical training for young men. There is probably no field of work in modern times where so great an amount of well-ordered experimental investigation has been undertaken as in engineering. Referring to the advantages of engineering workshops, Mr. Parsons said that knowledge, more especially of the practical kind, must be acquired when a man is receptive, and at such an age when ideas and impressions become so ingrained as to constitute intuitive and guiding principles in after life. In the engineering laboratory students are brought face to face with materials and machinery for dealing with and discovering principles; they gradually acquire a familiarity with practical engineering and the power to think in engineering materials, and to form a mental picture when it is necessary to design a new or improve an old machine or to design new methods of work. Such a training fits a student to go out into the world with mind and eyes alert, ready to acquire more knowledge, and fit to command success in most branches of engineering. By the help of good technical training a much larger proportion of men of high standard are produced than formerly—men of knowledge capable of taking the lead and commanding, and able and willing to deal fairly with their subordinates.

THE executive council of the County Councils' Association has made a series of recommendations with regard to rural education. They follow the main lines of the proposals of the Departmental Committee on Agricultural Education, which reported two years ago. Among other plans, the council encourages the formation of separate agricultural committees appointed by the county education committees. Another proposal is to appoint, in consultation with the agricultural college with which the county may be associated, a resident agricultural instructor and adviser at a salary of not less than 500*l.* per annum, who shall be under the control of the county council. The duties of this officer will be to give courses of lectures during the winter months; to supervise experiments and demonstration plots; to visit farms, small holdings, or allotments, and advise as to the appearance of disease in crops, insect pests, and on other matters; to meet bodies of farmers at local exhibitions and shows for the purpose of discussion; to organise classes for instruction in farm labour subjects and prize competitions in connection with such subjects as hedging, ditching, and thatching; and to advise the committee as to the establishment of permanent centres for agricultural instruction. It is also suggested that each county should organise, with the aid of the agricultural adviser, developments of a semi-educational character in connection with cooperative small holdings, instruction in pig-breeding, the establishment of poultry societies for improving breed and management, the provision of instruction in bee-keeping, the establishment of demonstration small holdings, the provision of a central county garden with demonstration and experimental centres for horticulture, and the provision of a demonstration farm of 100 to 300 acres, which might be used later as the nucleus of a farm institute. The association estimates that 2000*l.* per annum will be needed as a commencement, and suggests that an application should be made for a grant of this amount. The association has adopted the view of the Departmental Committee that "agricultural education is of such vital importance to the United Kingdom that no effort should be spared in making the provision for it as full and complete as possible," and that a complete system of technical agricultural education is "the natural corollary to the vast sums spent on elementary education in the rural parts of the country."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 3.—Sir Archibald Geikie, K.C.B., president, in the chair.—Sir D. **Bruce** and others: (1) Trypanosome diseases of domestic animals in Uganda. II.—*Trypanosoma brucei* (Plimmer and Bradford). (2) Trypanosome diseases of domestic animals in Uganda. III.—*Trypanosoma vivax* (Ziemann).—H. G. **Plimmer**, W. B. **Fry**, and H. S. **Ranken**: Further results of the experimental treatment of trypanosomiasis: being a progress report to a committee of the Royal Society. This paper gives detailed results of the continuation of the work which has been going on under the direction of a subcommittee of the Royal Society. The general results have confirmed an opinion which the authors have before expressed, viz. that antimony is a more powerful trypanocide than arsenic, and that such compounds as they have tried have not shown such severe toxic effects as some arsenic compounds have. But there are unpleasant effects produced (varying according to the animal used) by antimony, such as sloughing and necrosis at the seat of injection and severe pain, so they have devoted considerable time to the study of new methods and new forms of antimony. Finding that in dogs the subcutaneous and intramuscular administration caused pain and sloughing of the tissues, intravenous injections of the salts were tried. The elimination of the antimony was so rapid, however, that, beyond prolonging life, little good effect was produced; so that eventually the injection of the metal itself, in state of finest division (devised and prepared for them by Dr. R. H. Aders Plimmer, of University College), was tried. This is taken up by the leucocytes, and is gradually transformed into some soluble compound, and their idea was that perchance it might be carried to parts of the body not easily accessible to other methods of administration. The results so far have been, on the whole, more satisfactory than those of any other means they have tried, but the technique in many animals is difficult, and there have been difficulties in the preparation of the antimony. Although putting a metal into the circulation sounds impossible, they have not had any case of plugging of capillaries in rats, guinea-pigs, rabbits, dogs, goats, or horses. It of course acts much more slowly than the salts, and takes from two to three times as long to clear the peripheral circulation of trypanosomes as subcutaneous injection of a salt does. But the excretion is also much slower, so that the blood and organs are in much longer contact with antimony than when a salt is administered. If carefully administered no irritation of the tissues is produced, and the vessel walls are not affected. Animals appear to be more susceptible to overdosage than with the salts; and it is curious that an animal with trypanosomes in the blood can bear well a dose which is fatal to a healthy animal. It has also been used intraperitoneally successfully in rats and rabbits. A number of experiments have been made with silver salts, with negative results in every case. A number of experiments have been made with two new compounds (one an arsenic-camphor compound, one an organic antimony compound) kindly sent to them by Dr. Morgan, of the Imperial College of Science, with negative results.—Dr. J. W. W. **Stephens** and Dr. H. B. **Fantham**: The peculiar morphology of a trypanosome from a case of sleeping sickness, and the possibility of its being a new species (*Trypanosoma rhodesiense*). The main points of the paper may be thus summarised:—(1) This trypanosome was first observed by one of the authors (J. W. W. S.) in February in the blood of a rat infected from a case of sleeping sickness. (2) The patient, W. A., infected in Rhodesia, had never been in *Glossina palpalis* areas, though he had been in areas infested with *G. morsitans* and *G. fusca*. (3) The trypanosome shows long forms and short stout or stumpy forms with hardly any free flagellum, *but it is unique in that about 6 per cent. of the forms have the nucleus at the posterior* (non-flagellar) end *near the blepharoplast, and in some cases actually posterior to it.* (4) Such forms have not been described before in any known strain of *T. gambiense*. (5) Prolonged search has been made for them in the stock laboratory strain of *T. gambiense*, but they have not been found. (6) They are not due to the drying of the blood films, because they can be seen by *intra vitam* staining, and because dried films of the ordinary *T. gambiense* strain do not show them. (7) They are not degenerate, as division forms of them occur. (8) They are not due to drug treatment, because the original animals were inoculated before treatment was begun. (9) These forms still persist in rats, guinea-pigs, rabbits, and monkeys. (10) On morphological grounds the authors believe they are dealing with a new species of human trypanosome also causing sleeping sickness, for which they propose the name *T. rhodesiense*.—Dr. F. W. **Mott**: Notes upon the

examination, with negative results, of the central nervous system in a case of cured human trypanosomiasis. A Sikh belonging to the 4th K.A.R. (aged thirty at death) was found to be suffering from trypanosomiasis in June, 1905, and received treatment with inorganic arsenic. The drug was given intermittently for eighteen months or more, and pushed until toxic symptoms of neuritis and mental dullness rendered further energetic treatment impossible; trypanosomes were then no longer obtained by puncture of the glands. Unfortunately, there is no note of lumbar puncture having been performed until a few months before death. Sir David Bruce, in December, 1908, saw this man, and stated that he appeared to be in excellent health. A year later he was seen by Captains Hamerton and Bateman, who reported no symptoms of sleeping sickness. They made a very careful investigation of the blood, both by microscopic examination and by experimental injection into monkeys; the results were negative. In June lumbar puncture was performed, and 17 c.c. of fluid withdrawn; the centrifuged fluid showed no lymphocytosis or trypanosomes; injection of the fluid into a monkey was followed by negative results. The patient was attacked with pneumonia in August, and died three days after admission to the hospital. *Post mortem* the brain was found quite normal in appearance, and there was no excess of fluid. *Histological Examination.*—Sections were prepared of portions of the cerebrum, cerebellum, and medulla oblongata by all the methods which the author had previously adopted for the examination of sleeping-sickness cases. He found no trace of the characteristic meningeal and perivascular infiltration nor of gliosis. It may therefore be asserted that this case proves that human trypanosomiasis is curable, but it does not prove that sleeping sickness is curable, for the author contends that the diagnosis of "sleeping sickness" can only be made when there is a proof that the trypanosomes had invaded the sub-arachnoid space. The tissues were forwarded to the author by C. A. Wiggins, the acting principal medical officer of Uganda.—Miss M. P. **Fitzgerald**: The origin of the hydrochloric acid in the gastric tubules.—Dr. A. **Harden** and R. V. **Norris**: The fermentation of galactose by yeast and yeast juice (preliminary communication).—W. M. **Thornton**: The opposite electrification produced by animal and vegetable life. —R. **Kirkpatrick**: A remarkable pharetronid sponge from Christmas Island.

Challenger Society, October 26.—Dr. A. E. Shipley in the chair.—Mr. **Earland** exhibited and made remarks upon *Pilulina jeffreysii*, a rare species of Foraminifera dredged west of St. Kilda by the *Goldseeker*, which had only been recorded once since its discovery by the *Porcupine* in 1869.—Mr. Tate **Regan** discussed the evolution of the flat-fishes, which he regarded as asymmetrical perches; from some form not unlike Psettodes, indifferently dextral or sinistral, had arisen two well-marked groups, and each of these had split into two series, a sinistral and a dextral. Parker's researches on the optic nerves had made it clear that reversal to the asymmetry of opposite sign was secondary in the Pleuronectidæ.

PARIS.

Academy of Sciences, October 31.—M. Émile Picard in the chair.—The president announced the loss by death of D. Gernez.—Henri **Douvillé**: Some cases of adaptation. The origin of man. A discussion of some modifications produced in various species by change in the conditions of life, including changes which may possibly have been produced in the anthropoid apes by lower temperature, reduced rainfall, and consequent destruction of forests.—M. **Coggia**: Observations of the new Cerulli planet (KU) 1910, made at the Observatory of Marseilles with the Eichens equatorial of 26 cm. aperture. Observations are given for October 21 and 22, and also the positions of the comparison star.—H. **Larose**: The extinction of the discontinuities by reflection at the extremities of a telegraphic line. In a previous paper the expressions for the potential and current on a telegraphic line of indefinite length were given; the case of a line of limited length is worked out in the present communication.—G. A. **Hemsalech**: The influence of the magnetic field on the duration of the lines of the spectrum emitted by luminous vapours in the electric spark. In a magnetic field the durations of nearly all the lines are diminished, and the intensity of the action on the different lines appears to be selective. Nearly all the lines diminish in intensity except in the immediate neighbourhood of the electrode.—Georges **Claude**: The preparation of argon. Compressed oxygen prepared by the fractional distillation of liquid air is now an article of commerce. If the proportion of oxygen is more than 95 per cent., as is always the case in practice, the chief impurity is argon, the volatility of which is intermediate between that of oxygen and that of nitrogen. Since the oxygen is very readily absorbed, such a mixture forms an advantageous starting point for the preparation of argon.—L. **Gay**: The osmotic equilibrium of two fluid phases.—M. **David**: A method of analysis of fatty bodies by the separation of the solid fatty acids from the liquid acids. This method is based on the fact that, at a temperature of 13° to 14° C., the ammoniacal salts of the solid fatty acids are absolutely insoluble in a large excess of ammonia, whilst the ammoniacal salts of the liquid acids are completely soluble. Results are given of the application of the method to the separation of stearic or palmitic acid from oleic acid.—G. **Darzens** and H. **Rost**: The synthesis of ketones in the tetrahydroaromatic series. Cyclohexene is treated with an acyl chloride in presence of aluminium chloride, and the product of the reaction heated with an excess of diethylaniline. The physical properties of four ketones prepared by this method are described.—Em. **Bourquelot** and M. **Bridel**: A new sugar, verbascose, extracted from the root of *Verbascum Thapsus*. The mode of extraction employed is given in detail. The new sugar is analogous to stachyose, of which it would appear to be an isomer and from which it differs by its higher melting point and its greater rotatory power; it gives levulose, glucose, and galactose on hydrolysis.—G. **Friedel** and F. **Grandjean**: Liquids with focal conics. Liquids of the group of ethyl azoxybenzoate are characterised by the existence of groups of focal conics in their mass or at their surface.—P. A. **Dangeard**: Two lower organisms met with in the Roscoff laboratory.—A. **Imbert**: The influence exerted by pain on the form of ergographic diagrams of fatigue. —H. **Truc** and C. **Fleig**: The experimental and chemical ocular action of bitumen dust and vapour. Bitumen dust can rapidly produce various lesions of the eye in man. The condition of the eye before exposure is an important predisposing cause, and the action of sunlight is also prejudicial. The lesions resulting from the action of bitumen vapour upon the eye are comparatively slight. —M. **Urbain**, Cl. **Scal**, and A. **Feige**: The sterilisation of water on the large scale by ultra-violet light. The water is caused to circulate spirally round a source of light in such a manner that with a flow of 20 cubic metres per hour the water is exposed for three minutes to the rays. With this device complete sterilisation of water has been obtained with an expenditure of twenty watts per cubic metre.—Ch. **Gravier**: The duration of life in the Madrapores.—Henry **Pénau**: The cytology of *Endomices albicans*.—Y. **Deprat**: The geographical distribution of the different layers recognised in Yun-nan (Geological expedition, 1909–10).—Julius **Schuster**: The geological age of the Pithecanthropus of the pluvial period in Java. From a study of the fossil plants collected from the Quaternary deposits of Lasem, Java, the author is able to confirm his earlier estimate of the age of Pithecanthropus. If with Penck the age of *Homo heidelbergensis* be taken as 300,000 years, Pithecanthropus lived at least 400,000 years ago.—Louis **Gentil**: Geological sketch of the massif of Kebdana (Eastern Morocco).—E. A. **Martel**: The chasms of the Pyrenees. A short description of seven groups of subterranean fissures, eighty-four in all, together with a discussion of their effect on the water supply of the district.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 10.

ROYAL SOCIETY, at 4.30.—The Tidal Observations of the British Antarctic Expedition, 1907: Sir George Darwin, K.C.B., F.R.S.—Conduction of Heat through Rarefied Gases: F. Soddy, F.R.S., and A. J. Berry.—The Chemical Physics involved in the Precipitation of Free Carbon from the Alloys of the Iron Carbon System: W. H. Hatfield.—A Spectroscopic Investigation of the Nature of the Carriers of Positive Electricity from

heated Aluminium Phosphate: Dr F. Horton.—On the Determination of the Tension of a recently-formed Water surface: N. Bohr.—Aërial Plane Waves of Finite Amplitude: Lord Rayleigh, O.M., F.R.S.—Observations on the Anomalous Behaviour of Delicate Balances, and an Account of Devices for increasing Accuracy in Weighings: I. J. Manley.—On the Improbability of a Random Distribution of the Stars in Space: Prof. F. W. Dyson, F.R.S.—The Conditions necessary for Discontinuous Motion in Gases: G. I. Taylor.—(1) On the Radium Content of Basalt; (2) Measurements of the Rate at which Helium is produced in Thorianite and Pitch-blende, with a Minimum Estimate of their Antiquity: The Hon. R. J. Strutt, F R.S.

MATHEMATICAL SOCIETY, at 5.30.—Annual General Meeting. — The Relation of Mathematics to Experimental Science (Presidential Address): Sir W. D. Niven.—Properties of Logarithmico-exponential Functions: G. H. Hardy.—The Double Six of Lines: G. T. Bennett.—On Semi-integrals and Oscillating Successions of Functions: Dr. W. H Young.—On the Existence of a Differential Coefficient: Dr. W. H. Young and Mrs. Young.—The Analytical Extension of Riemann's Zeta-function: F. Tavani.—The Geometrical Representation of non-real Points in space of Two and Three Dimensions: T. W. Chaundy.—The Extension of Tauber's Theorem: J. E. Littlewood.—A Note on the Property of being a Differential Coefficient: Dr. W. H. Young.—The Stability of Rotating Shafts: F. B. Pidduck.—A Class of Orthogonal Surfaces: J. E. Campbell.—On Non-integral Orders of Summability of Series and Integrals: S. Chapman.—Optical Geometry of Motion: A. A. Robb.—Lineo-linear Transformations, specially in Two Variables: Dr. A. R. Forsyth.—On the Conditions that a Trigonometrical Series should have the Fourier Form: Dr. W. H. Young.—Notes on Terminating Hyper-geometric Series: Dr. W. F. Sheppard.—The Transformation of a particular type of Electromagnetic Field and its Physical Interpretation: H. Bateman.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Inaugural Address of the President: S. Z. de Ferranti.

SOCIETY OF DYERS AND COLOURISTS, at 8.—A Comparison between the Action of Dyeing, Tanning, and Vulcanisation: W. P. Dreaper.

FRIDAY, NOVEMBER 11.

ROYAL ASTRONOMICAL SOCIETY, at 5.—On the Formulæ for comparison of Observed Phenomena of Jupiter's Satellites with Theory: W. de Sitter.—Photographs of Halley's Comet taken with the Astrographic Telescope at the Cordoba Observatory: C. D. Perrine.—Third note on the number of Faint Stars with large Proper Motions: H. H. Turner.—(1) Mean Areas and Heliographic Latitudes of Sun-spots in 1907, 1908, and 1909; (2) Observations of Minor Planets in 1909; (3) Observations of Jupiter's Eighth Satellite in 1910: Royal Observatory, Greenwich.—*Probable Papers*: Preliminary Comparison with Observation of the Tables of the Four great Satellites of Jupiter: R. A. Sampson.—(1) The Systematic Motions of the Stars of Boss's "Preliminary General Catalogue"; (2) Note on a Moving Cluster of Helium Stars in Perseus: A. S. Eddington.

MALACOLOGICAL SOCIETY, at 8.—On the names used by Bolten and Da Costa for genera of Venerdiæ: A. J. Jukes-Browne, F.R.S.—On New Melaniidæ from Goram and Kei Islands, Malay Archipelago: H. B. Preston.—On the Anatomy of the British Species of the Genus Psammobia: H. H. Bloomer.—Note on *Triton tesselatus*: Major A. J. Peile.

PHYSICAL SOCIETY, at 8.—On the supposed Propagation of Equatorial Magnetic Disturbances with Velocities of the Order of 100 miles per second: Dr. Chree, F.R.S.—On Cusped Waves of Light and the Theory of the Rainbow: Prof. W. B. Morton.—Exhibition of a Brightness Photometer: J. S. Dow.

TUESDAY, NOVEMBER 15.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—The Castes of Eastern Bengal (Epidiascope): Sir H. H. Risley, K.C.I.E., C.S.I.

ZOOLOGICAL SOCIETY, at 8.30.—On the Inheritance of the Webfoot Character in Pigeons: J. Lewis Bonhote.—Notes on the little-known Lizard *Lacerta jacksoni* Blgr., with special reference to its Cranial Characters: Edward Degen.—On *Lacerta peloponnesiaca* Bibr.: G. A. Boulenger, F.R.S.—Remarks on Two Species of Fishes of the Genus Gobius, from Observations made at Roscoff: Edward G. Boulenger.

ROYAL STATISTICAL SOCIETY, at 5.—Presidential Address on a Statistical Survey of the Problems of Pauperism: Lord George Hamilton, G.C.S.I.

MINERALOGICAL SOCIETY, at 5.30.—Anniversary Meeting.—Further Notes on Wood-tin: J. H. Collins.—On the Alteration of the Felspar of Granites to China-clay: J. M. Coon.—On Wiltshireite, a new Mineral from the Binnenthal: Prof. W. J. Lewis.—A new Locality of Phenakite in Cornwall: A. Russell.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—Presidential Address on the Influence of Pure Science in Engineering: Sir J. J. Thomson, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Further discussion*: The London County Council Holborn to Strand Improvement, and Tramway-Subway: G. W. Humphreys.

WEDNESDAY, NOVEMBER 16.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Results of the Hourly Balloon Ascents made from Manchester, March 18th–19th, 1910: Miss Margaret White.—Registering Balloon Ascents, December 6th to 11th, 1909, and August 8th to 13th, 1910: W. H. Dines, F.R.S.—Pilot Balloon Observations in Barbados, December 6th to 11th, 1909: Charles J. P. Cave.—Report on Balloon Experiments at Blackpool: Capt. C. H. Ley.—Registering Balloon Ascents at Liverpool, June 21st to 23rd, 1910: W. Marriott.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Specimens of British Mycetozoa: A. E. Hilton.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, NOVEMBER 17.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: On the Effect of Gravity upon the Movements and Aggregation of *Euglena viridis* Ehrb. and other Micro-organisms: Harold Wager, F.R.S.—The Influence of Bacterial Endotoxins on Phagocytosis (including a new method for the Differentiation of Bacteria). THE CELLULOSE AGE.

Die Chemie der Cellulose unter besonderer Berücksichtigung der Textil- und Zellstoffindustrien. By Prof. Carl G. Schwalbe. Erste Hälfte. Pp. 272. (Berlin: Gebrüder Borntraeger, 1910.) Price 9 mk. 60 pfg.

THIS work is created by an opportunity, and in producing it the author has obeyed what in another walk of life would be a "call"—Germany not having produced a text-book or systematic work on this subject, the hiatus is a sufficient *raison d'être* for this publication. The author's qualifications as a worker in the field of cellulose promise a worthy fulfilment of his task, and we may say at once, the volume before us—the moiety of the work to be completed in and by a second volume, to appear at the end of this year—is a weighty contribution to the literature of this section of organic chemistry.

The general title presages a systematic treatment of the subject-matter; but the plan and method laid down are not critically selective, and the result is rather a classified account of original investigations, under sectional titles, such as "Cellulose and Alkalis," "Cellulose and Acids," "Cellulose and Salts," and "Colouring Matters" and "Oxidants," &c. The second part of the volume under the main title, "Derivatives of Cellulose," deals successively with "hydratcelluloses," "hydrocelluloses," "oxycelluloses," "hydracelluloses," "acid celluloses," &c.

The result is in effect a compilation, an edited bibliography. In recording this general impression we do not wish to detract from the value of the book; we merely note for the benefit of our fellow-students that there is a certain nonconformity of its matter with the title, and the promise of a pioneer work, which it contains, is still unfulfilled. The sub-title, "with special reference to the textile and wood pulp (zellstoff) industries," also fails to impress itself upon the plan or method of treatment, and therefore a dominating technical aim or *Leitmotiv* is no more in evidence than the critical scientific. The second volume yet to appear may modify these impressions; but we do not anticipate that the work will take rank otherwise than as an exhaustive bibliographical record. If we infer that this may be the author's intention, it is because we have no special or self-revealing preface (*Vorwort*), only a general introduction (*Einleitung*), and the reader is left to form his conclusions.

Following the short introduction in which technical rather than scientific generalities are prominent, we are confronted at once with the full complexity of cellulose in the title of section 1, "Die Baumwollecellulose Luft und Licht." To open with the problems connoted by this title is indeed to build from the top, upon foundations laid in the air. A merely *a priori* analysis challenges all we know *plus* a well-defined estimate of what we do not know of cellulose as a chemical individual, in being. The next section, "Baumwollecellulose und Elektrizität," continues to occupy the reader with problems of much complexity and obviously of the most general import. The phenomena and reactions involved are those of the cellulose aggregate, of which nothing can be affirmed. Section 4, "Die Baumwollecellulose bei Wärmezufuhr," continues the study of the aggregate in relation to energy. The series of decompositions presented by destructive distillation are infinitely varied, and pyrogenetic products of resolution are generally the least simply related to the parent substances or molecules; the author does not attempt this genealogical investigation.

We notice in passing that no mention is made either of the specific heat or heat capacity of cellulose, or of the physical phenomena, such as changes of volume and dimensions, within the range of temperature—*i.e.* up to 150°—which conditions the persistence of cellulose as a chemical individual. Since cellulose and many derivatives are now produced in the form of solids of regular and controlled dimensions, this important direction of physical investigation is opened up.

The following and main sections are devoted to the changes determined in the cellulose complex by the action of acids, alkalis, and salts and oxidants, and its relations to colouring matters and "mordants," generally to such compounds which enter into what it is now fashionable to call "adsorption" combination. It is particularly in the treatment of the complex phenomena attending hydration, hydrolysis, and condensation, that the author should have adopted a critical method. A "genial" drawing is worth a volume of photography, and if the author had trusted himself as impressionist rather than camera artist he would have used his great opportunity to more adequate purpose. No chemist regards "hydrocellulose," "hydracellulose," "hydratcellulose," "oxycellulose," as terms defining chemical individuals; they connote a more or less definite equilibrium of action and reaction within the cellulose aggregate, which is susceptible of infinitely varied "schemes" of degradation; these are better classified in relation to the determining conditions than in terms of presumed end-products. The alternative method, with the conscientious discharge of the duties of an "all-truistic" bibliographer, leaves the reader without mental pictures which are the pleasurable reward of the diligent student. Students of the natural sciences bewail a tendency to over-population of their book-world as of other "worlds." The literature of cellulose is already of formidable dimensions, and yet its fundamental chemistry can be set forth on the proverbial "half-sheet of notepaper."

The present phase of diffuse expansion in the region of "cellulose" and other typical colloids calls for a more critical attitude of workers and investigators, both in the researches undertaken and the extent of their records.

We may note in conclusion that the volume, in paper covers, weighs 733 grams. It involves therefore a considerable weight of cellulose; and, moreover, the printing and finish of the volume are unusually excellent.

D

DESCRIPTIVE METEOROLOGY.

Descriptive Meteorology. By Prof. Willis L. Moore, Chief of United States Weather Bureau. Pp. xviii+344. (New York and London: D. Appleton and Company, 1910.) Price 12*s.* 6*d.* net.

A TEXT-BOOK by the Chief of the great Weather Bureau of the United States of America will be received with not a little interest, and Prof. Willis Moore, in submitting this treatise, has had before him the definite aim of providing the young men entering the service of the bureau with "a comprehensive introduction to modern meteorology." We think that the author has in most ways successfully realised his aim, though the great prominence given to American methods and the researches of American official meteorologists make the work to some extent unsuitable for adoption as a text-book for students in other countries. The author warmly expresses his obligation for valuable help received from various colleagues—Abbe, Bigelow, Kimball, Henry, Cox, and Humphreys—and the extent of this indebtedness will be appreciated by those familiar with the writings of these specialists in the "Monthly Weather Review" and in various official bulletins of the bureau. We should have been glad, however, if attention had been directed somewhat more fully to the splendid work of A. L. Rotch, for a book such as this should be a source of inspiration to the student, and nothing in American meteorology is more inspiring than a consideration of the history of the Blue Hill Observatory.

To indicate briefly the scope of the work, we may say that the science of meteorology is given the widest possible reference, and that great attention is devoted to the dynamics of the subject. The opening chapters deal very fully with such general questions as the composition of the earth's atmosphere, the physical condition of the sun and its relation to the earth's atmosphere, and radiation waves in their different forms. Passing to a consideration of the vertical and horizontal distribution of temperature, a special chapter is devoted to an interesting study of the so-called "isothermal layer," where perhaps de Bort's term, "stratosphere," might have been adopted. A discussion of atmospheric pressure and circulation follows—where Buys Ballot's name is not mentioned—and Bigelow's work is summarised in considerable detail. Chapters on anemometry and the winds of the globe, on clouds, and on precipitation in its various forms, are good, but the international classification of clouds should have been included. Then follows an admirable discussion of weather forecasting, a chapter on meteorological optics, and a final one on climate—somewhat discursive, but excellent in its treatment of the influence of topographical conditions.

Prof. Moore is a master of the art of condensation and the fortunate possessor of a good sense of proportion, and these qualities have enabled him to cover a wide field in a satisfactory manner. The great organisation the work of which he directs touches the practical interests of the people at many points, and he is at his best in discussing the practical problems of weather forecasting, which are illustrated by an excellent series of weather maps. Again, his brief discussions of such questions of perennial popular interest as the influence of forests on rainfall and the supposed influence of the Gulf Stream on the climate of western Europe are excellent. It was perhaps well practically to exclude mathematical formulæ, but we think that here and there the book might have been strengthened by the inclusion of statistics in tabular form. Thus the vital differences between insular and continental climates would have been most forcibly brought home to the student by actual data for actual places along some given parallel of latitude across, say, the Eurasian continent.

Each chapter concludes with an excellent bibliography, but the attention of American students might have been directed to the research papers issued from the British Meteorological Office during the last few years. And the book properly ends with an index, but a glance at this leaves us puzzled as to what principle was adopted in the inclusion of proper names. Buchan and Rotch are merely mentioned in the book, and their names are not quoted, nor are those of Bigelow and Humphreys, though their work is laid under heavy contribution, whilst those of less well-known authors are given. In a book published in 1910 a different adverb should have been used in a reference (p. 194) to "Sir William Thomson (now Lord Kelvin)."

The publishers have done their work well and the volume is a handsome one. The numerous illustrations and charts are excellent, though the map representing the normal distribution of rainfall over the United States would have been more readily grasped had it been printed in different shades of colour instead of merely with red isohyets running over a white surface.

THEORIES AND PHYSICS OF THE SUN.

(1) *Les Théories Modernes du Soleil.* By J. Bosler, "Encyclopédie Scientifique." Pp. xii+370+xii. (Paris: Octave Doin et Fils, 1910.) Price 5 francs.
(2) *Vorlesungen über die Physik der Sonne.* By Prof. E. Pringsheim. Pp. viii+435. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 16 marks.

IN the first of these two books, dealing with our central luminary, the sun, the author presents his readers with a very well-arranged survey of the more modern views with respect to this important body. The author, who is one of the astronomers at the Meudon Observatory, is in a particularly good position to become acquainted with modern solar researches and opinions, and the solar work in progress at that observatory is second to none.

The book bears evidence of the author's command of his subject, and the method of placing the material before his readers which he has adopted is one that is highly commendable and particularly suitable for the valuable series of volumes which form this "Encyclopédie Scientifique."

Commencing with the general theories of the solar constitution, he makes a brief *résumé* of older views up to 1860, which include those of Herschel, Kirch-

hoff, Zöllner, Secchi, &c. Then at some length the circular refraction and anomalous dispersion theories by Schmidt and Julius respectively are discussed. The temperature of the sun comes next under review, followed by a chapter on the dynamic and thermal equilibrium of the sun. Lastly, the electromagnetic field of the sun and the theories concerning the corona are taken in hand, and the views of Schuster, Bigelow, Deslandres, Ebert, Nordmann, Arrhenius, &c., are contrasted. This chapter also includes an account of Hale's work on the magnetic field in sun-spots, and recent researches carried out at Meudon on the high level strata of the solar atmosphere.

The text is well illustrated with numerous reproductions from recent solar researches, and the volume contains good bibliographical author and subject indices.

(2) Prof. Pringsheim's book is the outcome of a set of lectures which extended over a series of years at the Berlin University. These lectures were not restricted to astronomical students only, so that the subject was dealt with in a little more popular manner than otherwise would probably have been the case.

The twelve lectures which form the subject of this volume comprise a comprehensive survey of the past and present views relative to the physics of the sun, and the author has managed to include a great deal of material in these lectures. The information has been brought well up to date, and the monochromatic work accomplished by the aid of the spectroheliograph in the hands of Deslandres and Hale has been thoroughly dealt with, and forms a valuable chapter. The volume is well illustrated, contains a great number of references, and is accompanied by useful subject and name indices. It will be found a serviceable book for students and a good readable volume for those who wish to become acquainted with the progress in our knowledge of the physics of the sun.

SOME ASPECTS OF PHYSICAL CHEMISTRY.

(1) *The Elements. Speculations as to their Nature and Origin.* By Sir William A. Tilden, F.R.S. Pp. xi+139. (London and New York: Harper and Brothers, 1910.) Price 2*s.* 6*d.* net.

(2) *The Relations between Chemical Constitution and Some Physical Properties.* (*Text-Books of Physical Science.* Edited by Sir William Ramsay.) By Prof. Samuel Smiles. Pp. xiv+583. (London: Longmans, Green and Co., 1910.) Price 14*s.*

(3) *Physical Chemistry. Its Bearing on Biology and Medicine.* By Prof. James C. Philip. Pp. vii+312. (London: Edward Arnold, 1910.) Price 7*s.* 6*d.* net.

THE discovery of radio-activity has, by the introduction of a new idea, reawakened interest in many outstanding problems of physical science. Prominent among these is the fascinating question of the nature and origin of the elements. Chemists with the periodic table of Mendeléeff before them, in spite of the warnings of its author, have been unable to resist the idea that some close genetic relation exists between the different elements of the nine groups of which the table consists, certainly along the vertical lines and probably also along the horizontal series. As to the nature of this relationship, nothing very definite was known or even imagined beyond the fact that it was accompanied by increase in atomic mass, and the probability that it was the result of condensation of some primal matter or protyle, under the influence of changing conditions, of which temperature was possibly one of the chief factors.

(1) The effect of recent work on the views entertained by chemists on this question forms the subject-matter of the latter portion of Sir William Tilden's book, the former half being devoted to a brief and clear exposition of the ideas which led to the formulation of the periodic law. The interesting account given of the various theories of the evolution and constitution of the elements which have recently been proposed culminates in a tentative and most suggestive genealogical table of the elements, which cannot fail to arrest the attention of all chemists. The author favours the idea that the elements of the seven chief vertical groups (with exception of the families headed by copper, chromium, and manganese) are directly "descended" from the seven elements from sodium to chlorine, the members of the odd and even series forming separate families with a common ancestor. The remaining elements (Group 8 and the exceptions just mentioned) are more or less directly descended from iron, which itself is placed in genetic relation with aluminium. The elements sodium to chlorine are direct descendants of the corresponding elements of lower atomic weight, lithium to fluorine, and these are themselves formed by the condensation of varying proportions of the two primal constituents of all matter, positive and negative protyle, as to the nature of which nothing is known. It is, moreover, by the addition of further amounts of these two primal substances that one element is derived from another of lower atomic weight.

Hydrogen is a progenitor of lithium, and a new unknown element, of atomic weight 3, is postulated as a precursor of fluorine. The elements of the zero group (the helium gases) are supposed to be by-products of the disintegration of elements of high atomic weight, possibly long extinct. In this connection it may be noted that the radium emanation is stated to be wholly converted into helium, a conception at variance with the generally received idea.

Such a scheme, in the nature of things, teems with doubtful points, and the author is to be congratulated on his courage in exposing his ideas to the shafts of criticism which are sure to be winged against them. His table, however, undoubtedly expresses much that has been vaguely in the minds of many chemists, and removes some of the chief difficulties inherent in the classification of the elements in the strict order of their atomic weights. Where it appears to be deficient is in the expression of the relations between the members of the horizontal series. It must also be remembered that the only positive evidence of genetic relationship at present

available, which is afforded by the disintegration of the radio-active elements, seems to indicate that devolution occurs primarily along the horizontal series, and that the highest known member of the helium group—the newly-christened niton—takes its place in the chain of descent along with the other elements, and cannot be regarded simply as a by-product.

Enough has been said, however, to indicate the great interest attached to this short work, and the service rendered by the author in presenting in a collected form the ideas of chemists, enriched by his own suggestions, on this fundamental problem of the science.

(2) Dr. Smiles treats of a subject much more amenable to experiment than the disintegration of the elements, and the perusal of his bulky volume shows how difficult it is to arrive at any but empirical relations between physical properties and chemical constitution, even when the effect of every minute change in constitution can be examined experimentally. The work deals with the chief physical properties of the elements and their compounds (with certain exceptions which have already been considered in other volumes of the series), and provides an extremely useful compendium of the work which has been done in this connection. The author has, however, not allowed his subject, great as is the mass of detail comprised in it, to overwhelm him, but has throughout paid special attention to the applications which have been made of the knowledge acquired to the solution of problems of constitution, and to the effect of progress in this branch of the subject on the general trend of chemical theory. The interest is further increased by a preliminary clear account of the nature of each physical property in turn, and a historical sketch of the progress of knowledge with regard to it. The author's final conclusion that further advance will depend essentially on a more complete solution of the problem of valency will probably commend itself to most chemists, and there seems little doubt that, as foreshadowed in many parts of this book, the study of physical properties will be an important factor in the attainment of this result.

In his exposition of the general principles of physical chemistry (3), Dr. Philip has aimed at giving an account of the subject which will be of special value to workers in the borderland regions of biology and chemistry, and has therefore adapted his book both in scope and treatment to attain this end. Without any sacrifice of scientific accuracy, he has given a sound and readable account of the subjects of chief interest to biologists, and has illustrated them wherever possible by reference to problems of a biological nature. In addition to the ordinary fare of works on elementary physical chemistry, special attention is paid to osmosis, permeability and impermeability of membranes, the properties of colloids and adsorption. On the whole, the author has succeeded admirably in his purpose, and has provided a valuable and interesting introduction to the subject, not overburdened with detail and almost free from those mathematical subtleties which are too frequently the despair of biologists.

ARTHUR HARDEN.

CHEMISTRY FOR FIRST-YEAR STUDENTS.

(1) *A College Text-book of Chemistry.* By Prof. Ira Remsen. Second edition, revised. Pp. xxiii+702. (London: Macmillan and Co., Ltd., 1908.) Price 10s. net.

(2) *Outlines of Chemistry. A Text-book for College Students.* By Prof. Louis Kahlenberg. Pp. xix+548. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1909.) Price 11s. net.

(1) THE first edition of Prof. Remsen's "College Chemistry" was somewhat unfavourably reviewed in these columns [NATURE, vol. lxv., p. 314 (1902)], and, unfortunately, most of the faults then pointed out recur in the present edition. Notable exceptions are, however, the treatment of the ionic hypothesis and of the determination of molecular weights from measurements of osmotic pressure. The least satisfactory portions of the work are those dealing with physical and electro-chemistry. Even on the purely chemical side there are some passages which might be amended. Thus it is not generally true, as stated on p. 144, that metals can be distinguished from non-metals according to whether they do or do not liberate hydrogen from hydrochloric acid to form chlorides. (A better criterion is, however, given on p. 169.) On pp. 185–6 volumetric analyses are calculated on the objectionable system based on a consideration of the weights of the reacting substances in the respective measured volumes, instead of by the straightforward "equivalent" method.

These faults are the more to be regretted since the book is in many ways admirably suited for the purpose for which it is intended. Thus Chapter V., dealing with the atomic theory and the determination of atomic and molecular weights, is, for the most part, a model of clearness. Attempts have been made to bring the work up to date by the insertion of short references to the phase rule, catalysis, the electron theory, radioactivity, &c. Within the scope allowed, the systematic descriptive portion is excellent. The experimental exercises given at the end of each chapter are well chosen; but, unfortunately, few first-year students in this country would have the time or the laboratory facilities for carrying them out.

(2) Prof. Kahlenberg's book is, like the preceding, intended for first-year students, and of necessity covers much the same ground; but there the resemblance ends. The general plan, as set forth in the preface, is to lead up to general theories through the fundamental facts and laws instead of first laying down general propositions and then illustrating these by facts. Accordingly, no mention of the atomic and molecular theories or of chemical nomenclature and symbols is made until the sixth chapter is reached.

Physical chemistry does not occupy a prominent place in the book; nevertheless, seeing that Prof. Kahlenberg is practically the only opponent of the generally accepted ionic hypothesis to be taken seriously, we turn with interest to the pages dealing with this part of the subject. On p. 429 we find the remark: "The main difference between the Clausius and Arrhenius theories is that the latter assumes the

presence of a very much larger percentage of dissociation"; and on p. 432, "The reader will have no difficulty in comprehending books that still use the nomenclature of the theory of electrolytic dissociation by remembering that the term *ion* as used in expressing chemical change means the same as atom or radical" (*sic*).

The periodic law is discussed in Chapter XX., but in the arrangement of the descriptive matter it is entirely ignored. This is a great drawback, as inorganic chemistry without the periodic law and the ionic hypothesis becomes a mere jumble of disconnected facts, difficult to remember, and still more difficult to assimilate. Otherwise the book contains as much pure chemistry as a student of medicine or engineering, who can devote only one year to the subject, requires. There are also short accounts of the chief processes in applied chemistry.

OUR BOOK SHELF.

Super-organic Evolution. Nature and the Social Problem. By Dr. E. Lluria. With a preface by Dr. D. Santiago Raman y Cajal. Translated by Rachel Challice and D. H. Lambert. Pp. xix+233. (London: Williams and Norgate, 1910.) Price 7s. 6d. net.

"MAN is a product of universal mechanics."

"*The solution of the social problem is contained in the law of evolution.*"

"There exists an irrefragable law which has made man out of a conglomeration of matter, and this same law, sooner or later, will have to be followed, in order that man himself may attain the state of happiness that is his legitimate aspiration."

These aphorisms lie at the root of Dr. Lluria's philosophy. The researches of Don Santiago Raman y Cajal into the phylogeny and ontology of the nervous system have greatly impressed him, and a third of the volume is occupied with an account of them. He assumes that the nervous system of man will continue to increase in complexity. "The brain of man still continues its psychic evolution." While agreeing that this is "a conclusion of paramount value," we fail to trace the logical steps by which it is reached, and the same may be said of the further inference, "In society, super-organic organism, the rapidity of change will be greater than in any other."

With the best will in the world, it is not easy always to follow the author, as, *e.g.*, when he tells us that "Society lives in a profound error as to property. It has chosen the paltry medium of money instead of the grand inheritance of Nature, which belongs to it by right, confirmed by the theory of evolution." But it is not only society that is to blame. "The responsibility falls particularly on many men of science who have not understood the theory of evolution, giving it, for example, such a false and iniquitous interpretation as *the struggle for existence*—a dreadful distortion of the natural course of ideas."

It is unfortunate that the translator is evidently unfamiliar with the technical terminology which is inseparable from a treatise of this description. There is no index.

The Romance of Modern Astronomy, describing in Simple but Exact Language the Wonders of the Heavens. By Hector Macpherson, Jun. Pp. 333. (London: Seeley and Co., Limited, 1911.) Price 5s.

COMMENCING with a chapter on our place in the universe, the author proceeds in the established sequence with chapters on the earth's motions, the sun, Mercury, Venus, &c., completing the discussion of the solar system with comets and shooting-stars. At more remote distances the suns of space, stellar motions and systems, and nebulæ are the subjects claiming the writer's pen. Some forty pages are devoted to tides, the spectrum and other incidental subjects, while five chapters deal with popular aspects of astronomical history.

The treatment, though generally clear and accurate, seldom rises above the commonplace. A feature which cannot be commended is the persistent introduction of somewhat lengthy quotations from other writers on astronomy. This method of providing "purple patches" discounts the individuality of the writer, whether it be due to modesty or otherwise.

Though steering clear of error in his elementary exposition, the author is not guiltless of loose statements, such as that silver-on-glass reflectors "have a light-gathering power far exceeding the telescopes whose mirrors are constructed of speculum metal."

Many of the illustrations are new, and, on the whole, well done, the artist being successful in finding picturesque settings for some of the more common astronomical happenings. The frontispiece, however, is very misleading; here an enlarged drawing of the head of Halley's comet fills the picture above a portion of landscape, put in doubtless for effect, the whole giving the impression that the coma stretched from zenith to horizon.

The Practice of Soft Cheesemaking. A Guide to the Manufacture of Soft Cheese and Preparation of Cheese for Market. By C. W. Walker-Tisdale and T. R. Robinson. Second edition, revised. Pp. 94. (London: Office of the *Dairy World*, 1910.) Price 1s. net.

A SECOND edition of this little book having been called for, the authors have taken advantage of the opportunity for introducing a certain amount of new matter. With true commercial instinct, they have put in a section describing fully the preparation of Bulgarian sour milk and sour cheese, but their chief object is to give a number of recipes for making soft cheese—often known as cream cheese—likely to sell well and at a good profit.

Soft cheese is a much simpler matter for the producer than ordinary cheese. No great capital or strength are required; the uniformity desirable for butter-making is not needed, so that comparatively small volumes of milk suffice, and the best demand exists precisely at the time when milk is in greatest abundance, *i.e.* in spring and summer. It is therefore essentially a product that the small holder can go in for, and the recognition of this fact by the authors adds greatly to the value of the book. The process of manufacture is simple, and consists merely in adding rennet to milk or to a mixture of milk and cream, then separating the coagulum, and allowing it to drain. There are, however, numerous details that require attention, but these are fully set out.

The book will be found very useful for dairy students and small holders, as well as for the growing class of dwellers in the country who keep a cow for their own use.

Twelfth Report of the Woburn Experimental Fruit Farm. By the Duke of Bedford, K.G., F.R.S., and S. U. Pickering, F.R.S. Pp. iv+51. (London: Amalgamated Press, Ltd., 1910.) Price 1s. 7½d. (post free).

IN this, the twelfth report issued from the Woburn fruit farm, the authors deal with the silver-leaf disease of plums and other fruit-trees in the thorough manner that characterises all their work. This disease is caused by the fungus *Stereum purpureum*, but the

relationship is less obvious than usual, because the fungus only fructifies on the tree that it has killed, and the mycelial threads are only discoverable with difficulty on the living wood. The proof lies in the fact, well brought out in this report, that inoculation of a healthy tree with a piece of the fungus nearly always causes the disease.

As its name implies, the disease is characterised by the silvery look taken on by the leaves, due, apparently, to a disconnection of the cells. Changes in nutrition processes are, no doubt, the immediate cause, but it is suggested that the final cause is a poison formed during the growth of the fungal threads, which then spreads into the tree. This hypothesis explains, among other things, why the fungus is never found on the diseased leaves. The disease is usually fatal. All kinds of fruit are not equally susceptible; plums come first, followed by apples, laburnums, Portugal laurels, and pears as the least susceptible. If a tree recovers, it may still be badly attacked again; there was nothing to show that previous infection tends to immunise trees against subsequent attacks.

In New Zealand, where this disease is also troublesome, the application of ferrous sulphate is recommended as a remedy, but the authors cannot find that it is of any value. Indeed, no method of treatment seemed trustworthy, and all that the grower can do as yet is to burn affected trees and so prevent the disease from spreading.

Elementary Treatise on Physics, Experimental and Applied, for the Use of Colleges and Schools. Translated from Ganot's "Éléments de Physique." By Dr. E. Atkinson. Eighteenth edition, edited by Prof. A. W. Reinold, F.R.S. Pp. xiv+1225. (London: Longmans, Green and Co., 1910.) Price 15*s*.

ALL teachers and most students of physics know Ganot's "Physics," and will be interested in the appearance of another new edition. On examining the new volume they will find changes in the arrangement of subjects and chapters. In the section dealing with heat, the subjects of solution, equilibrium, and liquefaction have been put into separate chapters. Radiation is now dealt with under light. In numerous parts of the book extensive additions have been made, and much new matter on modern subjects of physics of great importance has been added. But to prevent an undue increase of size, sections dealing with matters of no interest to students of to-day have been omitted. In its new form the treatise is likely to continue its popularity. When another edition is necessary the editor should substitute a modern form of rain-gauge for that on p. 1146, and revise the section on the Gulf Stream on p. 1172, where several time-honoured fallacies are repeated.

Dunkelfeldbeleuchtung und Ultramikroskopie in der Biologie und in der Medizin. By N. Gaidukov. Pp. vi+83+Tafel v. (Jena: Gustav Fischer, 1910.) Price 8 marks.

THIS booklet gives a brief but fairly complete summary of the researches which have been pursued by means of dark ground illumination and the ultramicroscope in the domain of biology and medicine. Thus the structure of colloids and of "sols" and "gels" and the minute structure of various animal and vegetable cells as revealed by these methods are epitomised. But the methods themselves receive but the scantiest notice, the theory of the subject and the apparatus being dismissed in the space of a couple of pages. Those who desire to work at the subject will therefore have to seek instruction elsewhere. In some cases we do not think justice is done to ordinary methods of illumination; in Fig. 5, for example, a comma bacillus is depicted as being practically structureless when viewed by transmitted light, whereas with care a certain amount of structure can always be made out. Dark ground illumination no doubt does much to elucidate the finer structure of minute unicellular organisms; how far the ultramicroscope will help remains to be proved.

The work concludes with a very useful bibliography, and is illustrated with numerous figures in the text and five plates, two of which are coloured.

R. T. H.

LETTERS TO THE EDITOR.

The Limiting Line of Sedimentation in Wave-stirred Areas.

IF you can spare the space I think I can put your reviewer (October 6, p. 433) in the way of obtaining the information he seeks as to the "limiting line of sedimentation" in "wave-stirred areas." The presence of tidal and other currents is assumed.

In a paper to the Royal Society in 1882 I chanced to hit upon this limit, experimentally and incidentally, in the following observation:—

"Dried peas placed on a glass plate in a slight depression on a sandy bottom in 6 inches of water were rolled off by waves about 12 inches long and about 1 inch high. . . .

"Shorter waves $1\frac{1}{2}$ inches high had much less effect on them. A little sand that had collected on the glass was beautifully rippled with $\frac{1}{8}$-inch ripples" (Proc. Roy. Soc., 1882, p. 16).

According to this chance experiment the limit was rather more than half the wave-length.

In 1884 I submitted to the late Sir G. G. Stokes, F.R.S., the case of a soda-water bottle, trawled at about 40 fathoms in the English Channel, which exhibited evidence that it had been subjected to long periods of quiescence, with intermittent disturbance. Sir George Stokes replied in the very important letter published in my paper on the Skerries Shoal (Trans. Devon. Association, 1887, p. 498). For publication in the same paper I had asked Lord Rayleigh to give me some simple formula for ascertaining the practical limit of wave-action. His reply was:—

"For each step downward of $\lambda/8$ divide by 2·2." I may mention that λ represents the wave-length.

Now according to this formula the disturbance at a depth of half (or four-eighths) of the wave-length is about one-twenty-third of that at the surface, whereas at the depth of five-eighths it is about one-fiftieth. I believe that one-fiftieth is negligible, whereas one-twenty-third is not always so.

Thus the limit of disturbance lies between half and five-eighths of the wave-length.

This exactly agrees with my accidental tank experiment.

For further confirmation I may refer your reviewer to Stevenson's interesting discussion on the "Level assumed by Mud a Measure of Exposure" (Stevenson on Harbours, second edition, p. 16).

I will not trouble your reviewer with my own papers except to mention one in the Linnean Society's Journal, Zoology, vol. xviii., p. 263, "On the Influence of Wave-currents on the Fauna inhabiting Shallow Seas."

At the recent inquiry on coast erosion Mr. R. H. Worth cited a delightful zoological proof of a local limit of disturbance. Speaking of *Alcyonium digitatum* and several other hydroids, Mr. Worth stated that:—

"Somewhere below 35 fathoms they will attach themselves to light bodies; above 25 fathoms they will never

attach themselves to anything but heavy bodies" (Royal Commission on Coast Erosion, Ans. 4059).

A steady current has often no disturbing effect on the sea bottom, as the upper strata slide over the lower ones, but the slightest wave-action on the bottom, with its alternating currents, is most effective; and, as Sir George Stokes pointed out (I believe for the first time), the combined action of wave and tidal current may be very energetic, as in the case he cites, in which the combination of a steady tidal current of two miles an hour, combined with a reciprocating flow of one mile, would result "in a flow rapidly changing between one mile and three miles." I doubt whether this important fact had ever occurred to anyone else; and, up to the present time, no one has taken any notice of it, so far as I am aware.

Torquay. A. R. Hunt.

Two Notes from India.

I am writing to report a rather curious freak lily which I have lately seen out here. It was a garden variety, and it possessed a perianth of eight segments, which, however, is not unusual, but it also possessed eight stamens, the anthers of which were joined together in pairs, the remainders of these organs being separate. The union began about two-thirds of the way down from their apices, and from then up was complete. If any of your readers can suggest a cause I shall be glad to know it; I have never seen such a condition before. I may say that the rest of the organs were normal (there was only one flower on the plant), and both flower and plant were very healthy.

The second note which I might record as well, I think, though I know my statements about it will perhaps make some people doubt my veracity, is that while on duty one day, in the evening, about twenty miles away from Sangor, Central Provinces, in January a year ago, I was driving back through the jungle to Sangor about 7.30 p.m. when I distinctly saw what I consider to be an aurora borealis. The sun had set, and there was no moon out at the time. Suddenly faint streaks, and later distinct and many bright streaks, of light appeared across the sky, and I got out of the tonga and watched it about a quarter of an hour. There was continual vibration and movement of the light as a whole and of individual parts. The light was a plain white one, and very like a zig-zagged comb. No lights of any kind were near, nor could I see the fires or lights of any native villages except faintly in the distance, and these were quite distinct and easily distinguished from the sky phenomena. I pointed it out to my tonga wallah, who shook his head and said he did not know what it was. The stars were out, but that it was not a planetary light I am certain. I imagine the occurrence of this phenomena must be most uncommon in tropical countries, and I noted it in my diary.

Instruction in Methods of Research.

In Nature of November 3 appeared an address by Sir W. A. Tilden on modern scientific research.

The technical chemist may hardly agree with his conclusions that the art of scientific discovery cannot be communicated from one person to the other when the matter is considered in its wider aspect, and although it may be true that the great discoveries of the future will be made by the "inspired amateur," yet there is plenty of evidence that in Germany, at any rate, the general increase of knowledge and progress is to a great extent made up in detail work, without which it may also be stated that the great discoveries would never be made. Progress in this detail work to a great extent seems to be influenced, if not controlled, by training in research.

It is interesting to note that some authorities seem to have the impression that in this country the proportion of research men to chemists is higher than abroad.

In the columns of Nature and elsewhere I have previously advocated the teaching of the principles of research in class in all our chief colleges, and I believe that the student when entering them looks for some such training and expects it. This training would be of great value to the majority of chemists, who will naturally find their future work in industry. Its influence must be felt in the conduct of their future work.

The greater part of the time of the industrial chemist is taken up with dealing with unseen difficulties and overcoming them. This may not be research in its proper sense, but these difficulties can only be overcome in one way, and this when examined in detail will be found to be very similar, if not identical, with that necessary for the conduct of research. In fact, such work might be defined as the application of such principles of research to industry. It is not the application of ordinary academic chemical knowledge. That is certain.

So that with such a training, I would venture to point out, the man who has not that "combination of mental powers which is called insight" will derive great benefit, for it seems difficult to think that the student who has passed the entrance examination and gone through the college course can be entirely devoid of some such quality, even if he has not it to a superlative degree. The latter men must be trained, for has not Newton said that "zeal without knowledge is like expedition to a man in the dark"?

Some two years ago I put the question Sir William Tilden mentions of the establishment of central research stations for the chief industries before a textile society in the north.

It was then suggested that there were many difficulties in the way of a technical nature. One of the advantages of such a scheme would consist of the training which might be given to the younger men who are entering industrial work, and it may be that this could, to a great extent, take the place of the practical training in the colleges themselves, which Sir William Tilden, perhaps rightly, depreciates when it is carried too far.

W. P. Dreaper.

Royal Societies Club, St. James's Street, S.W., November 5.

The Armour of Stegosaurus.

Pardon me for saying that there is not the slightest reason to believe that the restoration of Stegosaurus with a double row of plates is incorrect, in spite of the statement of the reviewer in Nature for October 13. Not a single plate of this animal has been found with a symmetrical base, the base always being at an angle to the vertical axis of the plate; this implies that the plates were not placed on the median line, but to one side of it. Furthermore, in the only specimen in which anything like a complete series of plates has been preserved the linear extent of these plates is, roughly speaking, 40 feet, and it is a physical impossibility to arrange them in one series on 20 feet of back. These plates lie in position overlapping one another.

The only point at issue between Dr. Lull, who has studied the Stegosaurs most carefully, and myself is in regard to the arrangement of the plates. Dr. Lull believes that they were arranged in pairs. My own view is that, reasoning by analogy, they *should* have been thus arranged, but the facts in the case point to their having been placed alternately on opposite sides of the median line. No pair of plates has ever been found, and, making the greatest allowance possible for individual variation, it seems incredible that differences of several inches should exist between the plates from the two sides of the body if they were arranged in symmetrical pairs.

F. A. Lucas.

Museum of the Brooklyn Institute.

The above letter from Mr. F. A. Lucas shows that my apologies are due to the author of "Extinct Monsters and Creatures of Other Days." It is Marsh's restoration of Stegosaurus with a single row of dorsal plates that is incorrect, as was pointed out in a notice of Dr. Lull's restoration in the *American Journal of Science* for March, 1910, in Nature for the present year. In writing the review of Mr. Hutchinson's volume I must have trusted to memory, which played me false. R. L.

THE CARNEGIE INSTITUTION OF WASHINGTON AND ITS WORK.

QUESTIONS of the organisation, the objects, and the activities of the Carnegie Institution of Washington are of widespread interest. The demand, indeed, for popular and technical information concerning this institution is far greater than the available supply. It should be stated, however, that it is not practicable to explain in any brief compass the history of the development of so novel an establishment. There has been scant time thus far for those engaged in this development to step aside and write anything but an abstract of current events. It should be stated also that the complexity of the subject is much greater than might appear to casual observation. The institution has recently issued the eighth of its series of year-books, or annual reports. These year-books contain upwards of two thousand pages of condensed history, and when one considers that they embody what is probably the most complicated miscellany of contemporary literature, it may be seen to be no easy matter, even if one had the time, to gain first-hand knowledge by reading these books; and it may also be seen to be no easy matter even for one participating in their publication to give a comprehensive summary of their contents. Only the barest outline, therefore, of this history can be given in the present article, while some major and many minor considerations of interest doubtless to individuals may be referred to only casually or not at all.

On January 4, 1902, a committee of incorporators held a meeting in Washington, D.C., for the purpose of considering articles of incorporation, looking to the establishment of what was subsequently called the Carnegie Institution. This committee consisted of John S. Billings, Daniel C. Gilman, John Hay, Charles D. Walcott, Edward D. White, and Carroll D. Wright. Articles of incorporation were duly approved on the same date, and a board of trustees was thereupon elected. These included the President of the United States, the President of the Senate, the Speaker of the House of Representatives, the secretary of the Smithsonian Institution, and the President of the National Academy of Sciences as ex-officio members, along with twenty-two other members. On January 29, 1902, the trustees of the proposed institution assembled in the diplomatic room of the Department of State, under the chairmanship of John Hay, and received from Mr. Carnegie his recommendations for the foundation of the proposed institution, his outline of its general aims, and his deed of trust, by which he transferred in perpetuity to the trustees as an endowment fund 2,000,000*l.* worth of United States Steel Corporation bonds. These bonds bear 5 per cent. interest, payable semi-annually, so that the original income of the institution was 100,000*l.* In December, 1907, this endowment was increased by 400,000*l.*, so that the present income is 120,000*l.*

FIG. 1.—The Administration Building of the Carnegie Institution of Washington.

The institution was originally incorporated in accordance with the provisions of the laws of the District of Colombia, under the title Carnegie Institution. Subsequently, however, it was re-incorporated by an Act of the Congress of the United States, approved April 28, 1904, under the title of *Carnegie Institution of Washington*, which is now its corporate designation.[1] By this new Act of Incorporation, the institution was placed under the control of a board of twenty-four trustees, all of whom had been members of the original board referred to above. This

[1] The reader's attention may be called to the facts that the Carnegie Institute, located at Pittsburg, Pennsylvania; the Carnegie Foundation for the Advancement of Teaching, with headquarters in New York City; and the Carnegie Institution of Washington are separate and independent corporations.

board is self-perpetuating, but none of its members may be such by reason of official connection with

Fig. 2.—General View of Station of Department of Experimental Evolution, Cold Spring Harbour.

the United States Government or with other organisations. Thus the institution is now, like any other private corporation, neither subject to any special restrictions by, nor benefited by any special privileges from, the Government.

The trustees meet annually in December to consider the affairs of the institution in general, the progress of work already undertaken, the initiation of new projects, and to make the necessary appropriations for the ensuing year. During the intervals between the meetings of the trustees the affairs of the institution are conducted by an executive committee. This committee consists of seven members chosen by and from the board of trustees and the president of the institution, who is a member *ex-officio*, and acts as chief executive officer.

Amongst the aims of the institution specifically set forth in the founder's deed of trust are the following:—

(1) To promote original research, paying great attention thereto as one of the most important of all departments.

(2) To discover the exceptional man in every department of study whenever and wherever found, inside or outside of schools, and enable him to make the work for which he seems specially designed his life-work.

(3) To increase facilities for higher education.

(4) To increase the efficiency of the universities and other institutions of learning throughout the country, by utilising and adding to their existing facilities and aiding teachers in the various institutions for experimental and other work, in these institutions as far as advisable.

(5) To enable such students as may find Washington the best point for their special studies, to enjoy the advantages of the museums, libraries, laboratories, observatory, meteorological, piscicultural, and forestry school, and kindred institutions of the several departments of the Government.

(6) To ensure the prompt publication and distribution of the results of scientific investigation, a field considered highly important.

No great amount of reflection is needed to reach the conclusion that the fields of work thus clearly mapped out by the founder could not be entered without some difficulties. That the organisation of such an institution would be no easy matter might have been inferred also from the experience of the closely similar establishment, the Smithsonian Institution, seventy years earlier, for it may be recalled that the wisdom of the Congress of the United States debated the question of the proper functions of Smithson's foundation for a full decade before arriving at a definite programme for action. Even amongst those best qualified to judge of the merits of the ways and means available for the inauguration of this new enterprise, a great

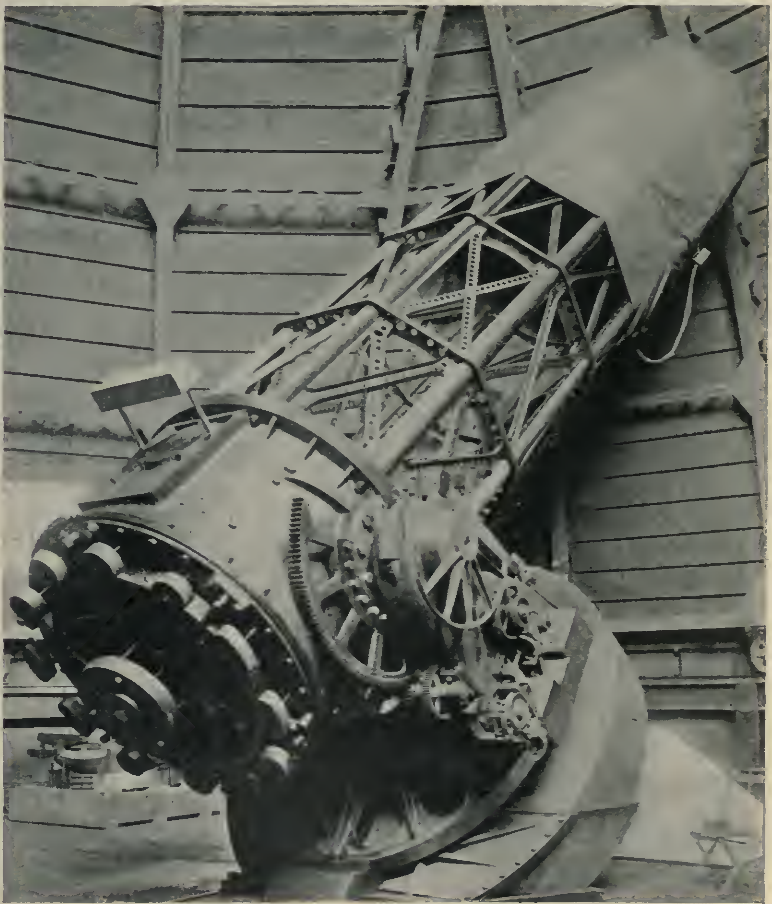

Fig. 3.—Sixty-inch Reflecting Telescope of Solar Observatory.

variety of opinions arose. Indeed, the volume of excellent advice and suggestion received by the

trustees of the institution during the first two years of its existence was overwhelming in abundance. The severity of the situation thus developed, however, was relieved by a humorous aspect found in the fact that it became possible to quote equally expert opinions on all sides of any question relative to the objects of the institution. In order, therefore, to accomplish anything in addition to correspondence it became necessary for the trustees to proceed in a way which has appeared in some degree arbitrary and without due regard to all interests concerned.

The productive activities of the institution have been developed thus far along four principal lines of work. These are, first, large projects organised under and conducted by the institution itself; secondly, minor projects carried on by individuals who are for the most part connected primarily with other institutions; thirdly, the work of research associates and assistants who are temporarily attached to the institution, and who are for the time being engaged chiefly in work of research; and, fourthly, the issue of publications, including especially the results of the investigations accomplished under the first three heads just mentioned, and the publication of investigations of special merit not likely to be cared for under other auspices.

Under the head of large projects, ten departments of work have been established. Two of these departments are devoted to astronomical investigations; three to research in biology; one to economics and sociology; one to research in geophysics; one to historical research; one to investigations in nutrition; and one to research in terrestrial magnetism. To these not inappropriately may be added the divisions in charge of the work of publications and the work of administration, making thus twelve different departments or divisions of work within the institution itself. Each of these principal departments of investigation is in charge of a director who is primarily responsible for the organisation and the conduct of the work entrusted to him. Annual appropriations are made to these departments in conformity with carefully specified budgets drawn up by the directors in cooperation with the president of the institution. Within the limits of his annual appropriation each director is given the largest freedom of action in the prosecution and in the development of the work he has in charge.

Under the head of minor projects many researches in widely separated fields have been undertaken by individual investigators. In round numbers about three hundred of these investigators have been connected with academic institutions. Similarly, limited numbers of eminent research associates have been and still are attached to the institution. In its earlier experience there were appointed also a limited number of research assistants, who were young men and women of promise, but had not yet demonstrated capacity for the accomplishment of fruitful research.

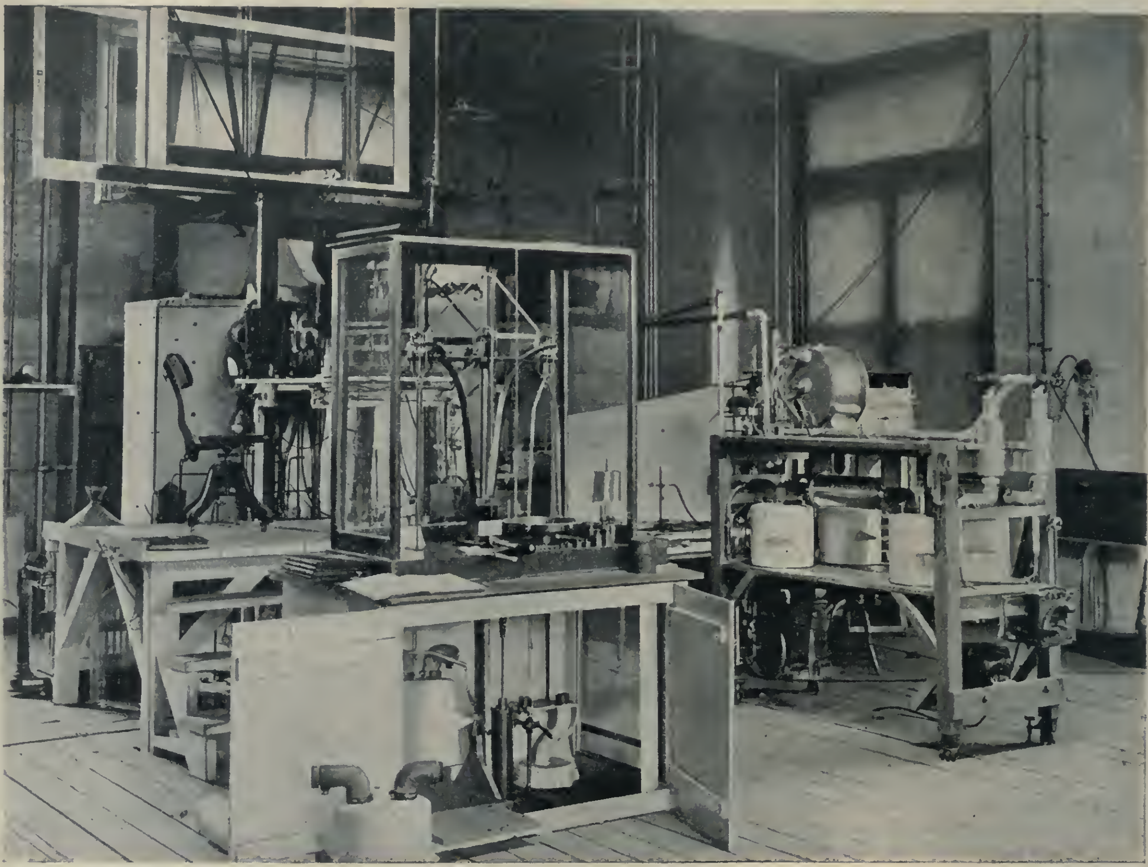

FIG. 4.—Interior View of Nutrition Laboratory.

Next in importance to the work of research is the work of publication carried on by the institution. For this object 10,000*l*. to 15,000*l*. are now allotted annually, and the institution is publishing books at the rate of twenty to forty volumes per year. These publications are distributed gratuitously to a limited list of the greater libraries of the world. They are

also offered for sale at the mere cost of production and transportation to purchasers, which cost is about half that which would be charged if the works were issued through commercial publishing houses. The expense entailed by this work prohibits the issue of large editions for free distribution; in fact, any attempt to meet the public demand for a free receipt of the institution's publications would speedily curtail the prosecution of research.

In addition to the productive work referred to above, there falls to the administrative division especially, in the institution, a large amount of unproductive work. This arises from a very general misapprehension as to the aims, objects, and capacities of the institution. Grossly exaggerated estimates of its income have generated, and tend to maintain, an

FIG. 5.—Non-magnetic Ship *Carnegie*.

extensive aggregate of fruitless correspondence. Deluded enthusiasts and designing charlatans, amateurs, dilettanti, arc-trisectors, circle-squarers, perpetual motion men and women, and all sorts of paradoxers press for endorsement, if not for pecuniary aid. It appears to be a serious defect of existing social conditions that there is no way of preventing those who have nothing to communicate to the world from interfering with those who have.

In closing this brief account of the institution, the effective work it has thus far accomplished may be summarily indicated by the following statement :—

Since its organisation, in 1902, upwards of one thousand individuals have been engaged in investigations under the auspices of the institution, and there are at present nearly five hundred so engaged. Ten independent departments of research, each with its staff of investigators and assistants, have been established. In addition to these larger departments of work, organised and conducted by the institution itself, numerous special researches, carried on by individuals, have been subsidised. Two observatories and five laboratories, for as many different fields of investigation and in widely separated localities, have been constructed and equipped. A building in Washington, D.C., for administrative offices and for storage of records and publications, was completed and dedicated in December, 1909. For ocean magnetic surveys a specially designed non-magnetic ship with auxiliary propulsion was constructed and put in commission during the year 1909. Work in almost every field, from archæology and astronomy to thermodynamics and zoology, has been undertaken, and the geographical range of this work has extended to more than forty different countries. One hundred and fifty-five volumes of researches, with an aggregate of forty thousand pages of printed matter, have been published. Upwards of one thousand shorter papers have been published in the current journals of the world by departmental investigators, by associates, and by assistants. The total amount of funds expended to date in the consummation of this work is, in round numbers, 900,000*l*. R. S. WOODWARD.

THE ROOSEVELTS IN AFRICA.[1]

NO one can read this interesting book by Mr. Roosevelt, sen., without realising how much the record owes to the work of Roosevelt, jun., of Kermit, the boy of nineteen to twenty who, before he had reached his twentieth year, had contributed some of the finest trophies to the expedition, who, though slight of build and boyish of aspect, confronted great dangers with calm resourcefulness, who took admirable photographs, and assisted the work of the expedition as a collector with the greatest zeal and usefulness.

The book under review is not without its defects and incongruities, and the expedition of which it is the record has received heavy censure from a good many people interested in the preservation of the world's fauna. Theodore Roosevelt, its author, has the defects of his qualities. His remarkable disposition and character have somewhat (as in the case of the late Sir Henry Stanley) prejudiced the judgment of a good many critics. In the first place, Mr. Roosevelt has not had sufficient leisure in which to do himself justice as the writer of a book on real natural history. Being a poor man when he left the Presidency, he was obliged, to a great extent, to pay the expenses of his very costly expedition by writing an account of it to be published week by week by the newspapers, a full diary, so to speak, of the day's events. Then, taking advantage of a brief rest at Khartum, he puts this diary together in book form, and has barely time to glance at the proofs before leaving England for the States in June. In addition to this, his publisher has thought it wise (and this reviewer feels bound to say that he thinks it unwise) to add to this work on natural history two speeches delivered by Mr. Roosevelt in Egypt and in London; while the author himself, not content with his wonderfully successful expedition and his own vivid appreciation of the African fauna and African landscapes, has further added, under the form of a dissertation on his "pig-skin" travel-library, a dissertation on the world's best books, ancient and modern.

[1] "African Game Trails." An Account of the African Wanderings of an American Hunter Naturalist. By Theodore Roosevelt. Pp. xvii+534. (London: John Murray, 1910.) Price 18*s*. net.

With the speeches delivered at the Muhammadan University of Cairo and at the Guildhall, London, the reviewer in NATURE has nothing to do, since they treat of politics, but he thinks they are out of place in a natural history book. They should have been published with the next volume of Mr. Roosevelt's public speeches, and with them should have been given the other side of the picture, the things he also observed but did not mention publicly, or, if he did so, were not reported by patriotic British stenographers or editors. As it is, these speeches do not give by any means a full statement of Mr. Roosevelt's views on Egypt. As to the "pig-skin library," it is perhaps a dangerous thing for a person of the world-wide influence of Theodore Roosevelt to set up an *index commendatorius* of books ancient and modern, with the inference that books dealing with the subjects he prefers, but not mentioned by him, are not worth the traveller's attention.

The fact is, that a second edition of this work should be brought out, stripped of these unnecessary appendices and the at first necessary, but after wearisome, records of thanks and obligations to a hundred-and-one personages. We should like to see Mr. Roosevelt's book take its place in the ranks with Bates's "Naturalist on the Amazons," Schillings's "With Flashlight and Rifle," and works of such character. He is a good zoologist and a peculiarly accurate and discriminating observer. Although he has traversed lands visited already by some of the great naturalist-explorers of the world, he has still made discoveries himself, or through others, and records a great many facts not hitherto known about the life-history of beasts and birds in equatorial East Africa. He is careful to note the seasons at which the young of different antelopes and other large game appear. He brings home to us, as no previous traveller has done, the extent to which this wild game is persecuted and infested with ticks, to which, however, they seem to have become so habituated that they dread them much less than the biting-flies, though the ticks are probably quite as much spreaders of disease, and even where they do not introduce disease germs must be extraordinarily weakening as blood-suckers. Many birds are devoting themselves in Africa to little else than the picking off and eating of the ticks and flies that infest the mammals. Where these birds are killed by European sportsmen, a great deal of future trouble is no doubt being prepared for us. For example (though I do not think this is mentioned by Mr. Roosevelt), certain types of heron (egret) are perpetually snapping at tsetse-flies, or other flies, which settle on oxen or game, and, if fully protected, might account for a considerable proportion of these disease-carrying creatures.

Photo.] [*Theodore Roosevelt.*

FIG. 1.—The Reticulated Giraffe. From "African Game Trails."

He has much that is new and interesting to say on the subject of the chita hunting-cat, really a little-known and little-studied carnivore in its wild state, both in Asia and Africa. The ordinary rhinoceros and its funny habits receive full illustration at his hands, and the square-lipped, white rhinoceros is revealed to us in its gentler, less aggressive disposition, as well as its association with the white egrets which, in accompanying it for its protection from ticks, whiten its broad back with their guano. (May this fact, equally possible in South Africa with the same kind of white heron, be an explanation of the otherwise absurd description "white rhinoceros"?) He pictures it for us in words, sitting down on its haunches like a dog (and, like its relation, the tapir), and shows us that due importance in description and pictures has not hitherto been given to the hump over its vertebræ at the shoulders. Grevy's zebra and the northern type of *Equus burchelli* (Grant's zebra) are rightly contrasted in appearance, habits, and cry. Some other peculiar features in both zebras, not hitherto recorded by naturalists, are set down here. Besides a good description of the vivid colours of the topi, or bastard hartebeest, he tells us that he has met with forms of the topi which develop a white blaze on the forehead. This is possibly a local sport, but is interesting as being a parallel to the white forehead of a southern type of topi, the blesbok. (This white forehead would seem to arise from exaggeration of the two white, frontal chevron marks which are liable to occur and re-occur in certain types of hartebeest and gnu.)

Mr. Roosevelt gives interesting particulars as regards the lion's method of killing most of the larger antelopes and zebra by springing on the back and biting through the vertebræ of the neck. It is possible that in the case of the stronger zebras or wild asses, the lion flings himself on to the neck itself and drags down the animal's head, biting at the vertebræ not far from the base of the skull. (This is well illustrated by a drawing in Mr. Millais's "Breath from the Veld.") In the case of full-grown buffalo, the lion's attack is generally made in concert, two or three young male lions, or a lion and lioness, working together, but also with the same object of severing the neck vertebræ. Failing this, attempts are made

to hamstring the beast by biting through the tendons of the hind legs, and once it is prone it is eviscerated by claws and teeth.

The alternation of the red-gold Jackson's hartebeest and the black and white Grant's zebra (looking silvery often in a slant of sunlight) is charmingly described; in fact, the book is full of verbal pictures, meet subjects for treatment by a painter. Indeed, on this score Mr. Roosevelt's remarks on the importance of pictures, as well as of photographs, in the effective illustration of wild life, are very sensible.

He describes to us the speed of the chita and its peculiar attitudes and cry, "a bird-like chirrup"; the dancing habits of the male widow-finches (Chera); "the rhinoceros standing in the middle of the African plain, deep in prehistoric thought"; the zebras and their stamping-grounds and their boldness in attacking dogs with teeth and hoofs, and not unreadiness to attack the white man also; the lions with their black and yellow manes (he might also have alluded to the frequency with which East African lionesses are boldly spotted with leopard-like markings, black below, and tawny-brown above); the large cuckoos "which eat mice," and the mice they eat, striped like miniature zebras; the fantastic little elephant-shrews with their probosces; the variety and beauty of the water-birds (not forgetting that creature of lovely tints, the ibis-stork, Pseudotantalus); the white-tailed ichneumons, never sufficiently hitherto commented on in descriptions of East African nature; the bold roan antelopes, with their large mouths and reported habit of biting as well as horning their foes, and squealing savagely when at bay. He gives interesting and precise information regarding the spitting-cobras, describing the venom as it is ejected through the point of the hollow tooth "like white films or threads." He quotes a fellow-traveller to the effect that the giraffe when fighting with other giraffes or other foes, makes little or no use of the short ossicones as a weapon, but strikes with the strong chisel-like teeth of the lower jaw, the blow being delivered with all the force behind it of the immense, heavy neck. The boldness of the hippo in regions where he has not as yet been taught to be afraid of man, is vividly described—the angry combats in the water between rival males, and the departure on shore of the vanquished bull, who, straight away, in a rhinoceros-like rage, attacks on land the native cattle, or even men and women crossing his angry trot. Roosevelt's notes on baboons, hyenas, elephants, white rhinoceroses, water-birds (especially p. 298), Grévy's zebra, white-bellied hedgehogs, the hyraxes, and the forest and mountain rats, are all most interesting, and in nearly every case novel, even to those acquainted with the East African fauna. Excellent in every way are his descriptions of the life of the savage men (invariably kindly towards this expedition), amongst whom and with whom he travelled. His descriptions of the botanical aspects of the country are full of colour and actuality, but are unfortunately marred here and there by the correctly described tree or plant being given the wrong name, either botanically or in the vernacular.

In short, Mr. Roosevelt has written a book which would have been quite as noteworthy and of as lasting

Copyright 1 no.o., [*Kermit Roosevelt.*

FIG. 2.—A Herd of Elephant in an Open Forest of High Timber. From "African Game Trails."

interest if it had been written by an unknown personage. But in its permanent form the relatively trivial press errors and slips of the pen should be corrected and all extraneous matter not connected with natural history, cut out.

The illustrations—drawings as well as photographs—are admirable. Mr. Roosevelt deserves praise for having carefully photographed the small mammals as well as the big.

Special triumphs of the expedition were the shooting by Mr. Theodore Roosevelt of the rare Somali reticulated giraffe, and by Mr. Kermit Roosevelt, of the East African sable antelope. In regard to this achievement, the writer of this review has enjoyed some satisfaction. In describing his own journey to Kilimanjaro in 1884, he stated that he had seen the sable antelope on the way thither. This statement was somewhat rudely derided by a succeeding traveller, who declared that the sable antelope was never found north of the region opposite Zanzibar Island.

H. H. JOHNSTON.

ATMOSPHERIC ELECTRICITY AND RAIN.

THE fact that raindrops often bring down a measurable charge of electricity has been known for twenty years, but numerical measurements have been comparatively few, and data of even moderate trustworthiness are scarce. A recent memoir of the Indian Meteorological Department[1] contains an account of the important work done on this subject in 1908 and 1909 by Dr. G. C. Simpson. This work is partly observational, partly experimental, and partly theoretical. To see its true bearing, reference is necessary to some other aspects of atmospheric electricity.

If we denote by v the electric potential at a height z above the ground, and if dv/dz represents the rate of increase of v with height just above ground level, then treating the conductivity of the air as negligible the earth must have a charge the surface density σ of which is $-(dv/dz)/4\pi$. In ordinary fine weather v increases as we go upwards, and so σ is negative. In practice one usually derives dv/dz from the difference of potential between two points in the same vertical one metre apart. This quantity, termed the *potential gradient*, varies much from day to day, or even hour to hour, and the average value seems to vary considerably at different parts of the earth. If, for example, we suppose it to be 150 volts, then remembering that the centimetre is the unit of length, and that the electrostatic unit equals 300 volts, we deduce $\sigma = -(1/4\pi)(1 \cdot 5/300) = -4 \cdot 0 \times 10^{-4}$ E.U. (or electrostatic units).

Atmospheric air is in reality not a perfect non-conductor. If one gives a body in air on a perfectly insulating support a charge, whether positive or negative, this is gradually lost. Of the numerous observations on the rate of loss of charge those made by Mr. C. T. R. Wilson, with an apparatus which he devised a few years ago, appear least open to criticism. In a paper published in 1908, Wilson[2] gives the result of a considerable number of observations on the loss of negative electricity under fine weather conditions. His mean rate of loss exceeded 8 per cent. of the charge per minute of time. In other words, a charge equal to the earth's charge at any instant was lost every twelve minutes. During these observations the mean value of the potential gradient was 187. This answers to a surface density of $-10^{-4} \times 4 \cdot 97$ E.U., or $-16 \cdot 6 \times 10^{-14}$ coulombs. Taking an 8 per cent. loss per minute, the loss per second—*i.e.* the value of an upwardly directed negative, or downwardly directed positive current—is $(8/60)10^{-2} \times 16 \cdot 6 \times 10^{-14}$ or $2 \cdot 2 \times 10^{-16}$ in amperes. If this represented average conditions, we should have in the course of a year from each sq. cm. of the earth's surface a loss of 7×10^{-9} coulombs, or 21 E.U. of negative electricity. During rain the potential gradient is often negative, but the total duration of negative gradient in the course of a year is not large. We are thus led to the conclusion that whilst 21 E.U. is probably an over-estimate of the charge lost annually per sq. cm. of surface by conduction through the air, it is unlikely to be much in excess of the truth unless the conductivity of the air is exceptionally high at times when the gradient is negative. The question thus arises: How is the earth's charge maintained?

Of the hypotheses advanced of late years, the one that has met with most approval is due to C. T. R. Wilson, who suggested that while districts enjoying fine weather are losing negative charge, other districts are deriving a corresponding amount of negative electricity from falling rain, the circuit being completed below by earth currents, and overhead by horizontal currents at a considerable height. Our knowledge of earth currents at the present moment does not enable us either to affirm or to deny a systematic transfer of electricity between wet and dry areas.

When Wilson's suggestion was made, it was believed that while the electricity brought down by rain was sometimes positive, still negative largely predominated, that being the result arrived at by Elster and Geitel, who were the chief of the early observers. Dr. Simpson's first contribution to the subject was the invention of an ingenious apparatus giving a continuous record of the amount and sign of rainfall electricity. This apparatus has been in operation at Simla during the monsoon or rainy seasons of 1908 and 1909, and the results are of an unexpected character. What the apparatus really does is to collect and record rainfall electricity for two-minute intervals. The data represent the total charges received for each successive interval and the corresponding rainfall. During the two monsoons 172·1 cm. of rain were recorded, with 44·0 E.U. of positive and 13·8 E.U. of negative electricity, or a balance of 30·2 E.U. of *positive*. The two-minute intervals during which a positive charge was measured amounted in all to 4·16 days, as against 1·70 days of negative. During about 37 per cent. of the total duration of rainfall no sensible charge was measured. Snow is rare at Simla, but for such snow as fell there was much the same relative excess of positive electricity as in the case of rain, the chief difference being that snow brought down more electricity than an equal weight of rain. An annual rainfall of 86 cm. is normal enough, and if the corresponding balance, 15 E.U., of electricity had been negative, it would have fitted Wilson's theory well so far; but being positive, it adds to the mystery respecting the source of supply of the fine weather current.

There are some features which raise doubts as to whether Simla phenomena are fairly representative. Rain there seems to be accompanied by much thunder and lightning, and the excess of positive electricity was especially prominent during the very heavy rain accompanying thunderstorms. In 1908, when rain was falling at a less rate than 0·17 inch per hour, the time during which negative electricity was recorded was about 90 per cent. of that during which positive was recorded, and the mean charge per c.c. was 2·2 E.U. for negative, as against 1·7 E.U. for positive, so that in the lightest

[1] Vol. xx., part 8, "On the Electricity of Rain and its Origin in Thunderstorms." By Dr. George C. Simpson, Imperial Meteorologist (also in Trans. and Proc. R.S.).

[2] Roy. Soc. Proc., A, vol. lxxx., p. 537.

rains negative electricity was slightly in excess. The charge per c.c. tended to be larger the lighter the rain, but the fall in two minutes was so small in light rains that it seems by no means improbable that with a more sensitive apparatus there would have been a smaller total excess of positive electricity recorded. Observations covering the complete annual precipitation, whether rain or snow, at a number of stations in different latitudes will be necessary before we can safely draw conclusions respecting the earth as a whole.

It was discovered by Lenard many years ago that in the case of an ordinary waterfall, or when water falls on a solid obstacle, the water drops formed take a positive, the surrounding air a negative charge. Lenard believed, however, that no such separation occurred when drops split up without falling on an obstacle. Simpson found a similar absence of charge when experimenting with Simla tap-water, but on trying distilled water he found that the splitting up of drops by means of a vertical air jet is accompanied by a marked separation of electricity, the water taking the positive charge. The breaking up of drops, each containing about 1/4 c.c. of water, gave the water a charge of about $+23 \times 10^{-3}$ E.U. per c.c. If the drops were already charged, this additional charge was added when they broke, so that the action is cumulative. Raindrops become unstable on attaining a certain size, and tend to break, so that natural conditions approach those of Simpson's experiments. A rational explanation is thus given of a positive charge on rain if it behaves as distilled water. This we should expect it to do, except perhaps in smoky districts, but further experiments on actual rain-water in various localities seem desirable. The presence on some rain of negative electricity is ascribed by Simpson to a transfer of charge from air which has previously surrounded breaking raindrops.

The theoretical problem mainly considered by Simpson is the relation of rain to thunderstorms. He believes that there are normally present in thunderstorm areas upward currents of air with velocities of at least 8 metres per second (18 m.p.h.). Such currents prevent raindrops from falling, and Simpson supposes the drops to go through frequent repetitions of the cycle; growth, breaking up (with separation of electricity), fresh growth, and so on, at a nearly constant height in the atmosphere until the charge is so great as to produce at a certain level a gradient larger than 30,000 volts per cm., which he takes to be the electric strength of air. When this limit is reached, a lightning flash neutralises the accumulated charge over a limited area, and the process goes on repeating itself. There are various difficulties in the way of accepting this explanation as complete, but some represent our present ignorance rather than positive knowledge. We should like to know, for instance, whether vertical air currents such as Simpson postulates really do exist near the precise level where the air breaks down, also what the true nature of a lightning flash is, whether unidirectional or oscillatory, what charge passes, and what is the expenditure of energy. For all we know, the air may be in a strongly ionised condition, possibly even there may be separation of the constituent gases, and a potential gradient much under 30,000 volts per cm. may suffice to cause a discharge. In the meantime, Simpson's theory of thunderstorms had better be regarded as a hypothesis, but, unlike some hypotheses, it promises to be useful in suggesting promising lines for observation and experiment. The separation of electricity by the breaking up of raindrops may not play quite so fundamental a part as Simpson supposes. but assuming it to take place with natural rain, it can hardly fail to play an important part in thunderstorm phenomena.

The memoir as a whole is most original and suggestive, and is one on which the meteorological service of India deserves to be congratulated. As many readers of Nature are doubtless aware, Dr. Simpson's services have been lent by the Indian Government to the present British Antarctic Expedition, principally with the view of his studying electrical conditions in high latitudes, and we may, I think, entertain high hopes that the resulting increase of knowledge will be eminently satisfactory both to India and to this country.

C. Chree.

THE PREVENTION OF PLAGUE.

A MEMORANDUM on plague has recently been prepared by Dr. Newsholme, medical officer of the Local Government Board, and has been sent to the sanitary authorities of England and Wales, with a request that their officers should endeavour to secure the adoption of the suggestions contained therein. The memorandum gives an interesting conspectus of the essential features of the disease, and deals mainly with its methods of spread and the measures which, in the light of recent researches, must be taken for its prevention. Fortunately, plague, although a disease capable of manifesting itself as an epidemic of a widespread and virulent character, is now so well understood on its epidemiological side, that the direction which preventive measures should take is obvious. The situation may be summarised in the dictum—"no rats, no plague." Practically, however, the matter is perhaps not so simple as it may seem.

The first section of the memorandum describes briefly the symptoms in plague. The injected eyes and the thick, "drunken" speech are noted as characteristic signs of the disease. There is no mention, however, of the tendency to "shouting" delirium and the impulse to get out of bed and wander off, utterly heedless of their condition—well-known symptoms in the natives of India. The "acute" ward of a plague hospital is at times a very noisy place, and mild restraint requires to be put upon patients to prevent their unconscious excursions.

The "ambulant" form of plague is referred to, and it is stated that persons with this type of the disease may spread the infection. Spread of infection by such persons would seem, however, to be very doubtful, by direct personal contagion at least, and it is equally doubtful whether effective carriers of the disease in the sense of typhoid carriers exist. The evidence for the existence of such carriers is not satisfactory, and although the possibility of the occurrence of "pneumonic" carriers must be considered, the rarity of this type, at least in India, and its extreme fatality, considerably limit its importance from this point of view.

The statement that there is little or no liability to infection from contaminated food is a comforting one, and is justified by the accurate observations on the pathology of human plague made some years ago in Bombay by the Austrian Plague Commission, and by the results of experiments on susceptible animals.

The memorandum accepts in its entirety the results of the recent investigations of the Plague Research Commission, viz., that the sole infective agents in an epidemic of bubonic plague to be reckoned with are the infected rat and the infected rat flea—the former an indirect agent and the latter the immediate infecting agent. It follows that the measures suggested for attempting to stamp out the disease are directed solely towards the destruction of rats and their parasites. It has indeed been claimed that domestic

animals, such as cattle, pigs, fowls, ducks, &c., are susceptible to plague infection, but extensive experiments made by competent observers in several parts of the world completely agree in opposition to this belief.

In the memorandum the importance of preventing the access of rats to or their entrance into buildings is emphasised. It is pointed out that a cat in the house is a safeguard against domestic invasion by rats and mice, although it must be borne in mind that the cat is in some degree susceptible to plague. Major Buchanan, of the Indian Medical Service, has strongly urged the advisability of stocking the villages in India with cats as a preventive measure, but it must be said that no very definite evidence in support of the proposal has been produced.

With regard to the extermination of rats it is admitted that complete extermination is perhaps impossible. A material diminution in the rat population would undoubtedly lessen the spread of infection amongst them, but the fertility of the rat and the fact that it overruns the whole country in enormous numbers make the task of permanently suppressing the rat community in this country an extremely difficult one. It is certain that only a never-ceasing and complete organisation for rat destruction will appreciably reduce their numbers, and it is perhaps not sufficiently realised by some of the advocates of a general rat campaign that in order to be thorough and effective such a campaign would involve a most extensive and, in the aggregate, a most costly organisation. In this connection the experience of rat destruction gained in Japan is instructive. Kitasato has reported that in five years 4,800,000 rats were killed *in Tokio alone* at a considerable financial outlay, but that at the end of this time no appreciable decrease in the rat population could be detected. Kitasato attributed this to the circumstance that the rate of destruction, vigorous as it was, did not keep pace with the natural increase in the rat population. Recent experience in India appears to point in the same direction.

It is beyond question, however, that so far as plague prevention is concerned a great deal can be done in this country by diminishing or, preferably, abolishing rat infestation in human habitations and in their immediate neighbourhood.

G. F. PETRIE.

DR. THEODORE COOKE.

WE announced with regret last week the death, on November 5, of Dr. Theodore Cooke, C.I.E., formerly a member of the Bombay Educational Department. Born at Tramore, co. Waterford, in 1836, Dr. Cooke entered Trinity College, Dublin, where, after a distinguished career as a student, he graduated in 1859 in the faculties of arts and engineering. In the former faculty he was Hebrew prizeman, first honoursman, and senior moderator and gold medallist in science; in the latter he obtained special certificates in mechanics, chemistry, mineralogy, mining, and geology. Pursuing his profession as an engineer, he joined in 1860 the service of the Bombay, Baroda and Central India Railway, then under construction; during this service he built for the company the great iron bridge at Bassein. Five years later the Government of Bombay secured the services of the talented young engineer as principal of the Civil Engineering College, which later with widened scope became the College of Science, at Poona. The post proved congenial to Dr. Cooke; his wide and varied knowledge, with which were associated much tact and great administrative gifts, enabled him to fill it with signal success until he retired from India in 1893.

Throughout his service Dr. Cooke had taken a keen interest in botanical studies, and field-work connected therewith was one of his chief recreations. What he did as a pastime was, however, characterised by the thoroughness that marked his official work; he soon became a recognised authority on the vegetation of Bombay and Scinde, and it was only fitting that when, in 1891, the Botanical Survey of India was organised, Dr. Cooke should be placed in charge of the survey operations in western India. Encouraged thereto by Sir George King, then director of the survey, Dr. Cooke made preparations for the production of a "Flora of the Presidency of Bombay." Difficulties over which neither Sir George King nor Dr. Cooke had control at first prevented the realisation of the scheme, and when Dr. Cooke retired in 1893 his energies found an outlet in a post to which he was appointed at the Imperial Institute.

The difficulties that had stood in the way of the publication of a local flora of Bombay having at last been overcome, Dr. Cooke was able, some years later, to settle at Kew and commence the preparation of the work in the herbarium there. The first part was published in 1901; the seventh and concluding part appeared about two years ago. The work is marked by the thoroughness and attention to detail characteristic of all that Dr. Cooke did; nothing is taken for granted; every previous statement is carefully verified or refuted; and the "Flora" will remain a lasting memorial to Dr. Cooke's critical acumen, industry, and energy. On its completion Dr. Cooke continued to work in the herbarium with undiminished ardour, assisting as a volunteer in the preparation of the great "Flora Capensis," edited by Sir W. T. Thiselton-Dyer, until laid aside by the illness which has ended his career. Dr. Cooke, on whom his university had already conferred the degree of LL.D., was created a C.I.E. in 1891, and was a Fellow of the Linnean and the Geological Societies.

NOTES.

THE Nobel prize for chemistry has been awarded to Prof. Otto Wallach, professor of chemistry in the University of Göttingen.

WE regret to see the announcement of the death, on November 13, of Mr. W. R. Fisher, formerly assistant professor of forestry at Coopers Hill College.

THE Royal Geological Society of Cornwall at its annual meeting at Penzance on November 8 awarded Dr. George J. Hinde, F.R.S., the Bolitho gold medal for his valuable papers and services in connection with the geology of the county.

A REUTER telegram from Pisa states that on November 10, in the presence of King Victor Emmanuel and a Government Commission, Signor Marconi received wireless telegrams direct from Canada and Massowah by means of his extra powerful installation at Coltano.

MR. A. E. BROWN, secretary of the Zoological Society of Philadelphia, has died suddenly of heart disease in his sixty-first year. He was vice-president and curator of the Academy of Natural Sciences in the same city, and a frequent contributor of zoological and biological articles to various scientific journals.

DR. C. WILLARD HAYES, chief geologist to the U.S. Geological Survey, is now visiting Panama by the direction of President Taft to make a preliminary study of

geological formations in the "canal zone," with special reference to the excavations at the Culebra cutting. Upon the results of his investigations will depend the decision whether a geologist will be permanently assigned to assist the canal commission.

A REUTER message from Munich announces the election of the following corresponding members of the Munich Academy of Sciences:—Dr. F. G. Kenyon, director and principal librarian of the British Museum; Dr. L. Fletcher, F.R.S., director of the Natural History Museum, South Kensington; Principal Miers, F.R.S., the University of London; Dr. D. H. Scott, F.R.S.; Profs. Wilson and Osborn, Columbia University, New York.

PRIOR to the anniversary meeting of the Mineralogical Society in the Geological Society's rooms at Burlington House on Tuesday, November 15, Dr. Lazarus Fletcher, F.R.S., was presented with his portrait, painted by Mr. Gerald Festus Kelly, in recognition of the invaluable services he had rendered to the society during the past quarter of a century, the presentation being made by Prof. W. J. Lewis, F.R.S., on behalf of the members and other subscribers. For three years, 1885–8, Dr. Fletcher was president, and for twenty-one years, 1888–1909, general secretary, of the society, and it is to his genial and stimulating influence that its present prosperous condition is largely due. Dr. Fletcher resigned the secretaryship upon his appointment as director of the Natural History Museum.

A CAREFULLY planned effort is being made by the authorities of the American Museum of Natural History in New York to popularise the resources of that institution. On a recent afternoon they gave a reception to from 1500 to 1800 of the school teachers of the city, having invited the principal of each school and two delegates whom he should appoint. The programme of this "Teachers' Day" included a personally conducted tour of the building, an introductory address by the president of the museum, Dr. H. F. Osborn, and six ten-minutes' talks by experts, interspersed by orchestral music, and followed by tea in the ornithological hall. The object of the reception was to show the teachers of New York what the museum had to offer both for themselves and for the children in their classes.

DR. W. H. BREWER, professor emeritus of agriculture at the Sheffield Scientific School of Yale University, has died at New Haven from the infirmities of old age. He was born in 1828. Before his appointment to the Yale chair in 1864 he had been professor of chemistry and geology at Washington College, Pennsylvania, and professor of chemistry in the University of California. He became professor emeritus in 1903. He had served on several important Government commissions, and had been president of the Connecticut Board of Health, of the Connecticut Academy of Sciences, and of the Arctic Club of America. In an editorial note on his career, the New York *Evening Post* describes him as one of the fast disappearing representatives of a stirring type. It quotes from a friend who once spoke of him as an "eminent geologist, an expert mining engineer, an Arctic explorer, an art critic, an author, and a charming companion," and adds that, like Shaler and Holmes, he "was the product of no system other than that prescribed by his own capacity of learning, and perhaps for that very reason possessed a vitality and range which are seen but seldom in the younger generation."

AT the annual general meeting of the London Mathematical Society, held on November 11, the following were elected to be the council and officers for the session 1910–11 (the names of members not on the retiring council are printed in italic type):—*President*, Dr. H. F. Baker, F.R.S., *vice-presidents*, *Mr. J. E. Campbell, F.R.S.*, Major P. A. MacMahon, F.R.S., Sir William Niven, K.C.B., F.R.S.; *treasurer*, Sir Joseph Larmor, F.R.S.; *secretaries*, Prof. A. E. H. Love, F.R.S., Mr. J. H. Grace, F.R.S.; *other members of the council*, Mr. G. T. Bennett, Dr. T. J. I'A. Bromwich, F.R.S., Dr. W. Burnside, F.R.S., Mr. E. Cunningham, Mr. A. L. Dixon, Dr. L. N. G. Filon, Dr. E. W. Hobson, F.R.S., *Prof. H. M. Macdonald, F.R.S.*, and Dr. A. E. Western.

VERY great vigour has characterised the conduct of the Tacubaya Observatory of late, and therefore the severe loss the institution has suffered by the death of the director, Dr. F. Valle, will be keenly felt, for he made the observatory a centre for scientific activity throughout all Latin America. Dr. Valle played a foremost part in promoting scientific usefulness and maintaining an efficient standard throughout the Republic of Mexico. The "Annuaire," for which he was mainly responsible, appeared with great regularity, and supplied a mass of information connected with geodesy, meteorology, and physics that would be particularly useful in the society in which it circulated, while the articles on astronomy quickened local and popular scientific effort. But of greater importance in general, and on what the reputation of the late director will rest, was his ardent prosecution of the work of stellar photography in connection with the *Carte du Ciel*, the observatory being responsible for the zone 10°–16° south declination. When the last report was issued, only 22 fields remained to complete the 1200 for the catalogue, and these must have long since been supplied. No fewer than 800 plates had been measured, and the catalogue plates were being actively pushed forward. Such activity contrasts very favourably with the results obtained at some observatories engaged on the southern zones, and the zeal displayed is the more commendable, as it is known Dr. Valle had to contend with very great difficulties in regard to the figure of the object-glass of his photographic refractor. Dr. Valle did not only measure his plates, but he used his meridian circle vigorously for determining the position of standard stars used in the reduction of the photographic plates. Add to this record the work of the observatory in spectroscopy, magnetism, seismology, and meteorology, and it will be admitted that Dr. Valle's energy went far to remove the stigma of indifference and lassitude which at one time was inclined to rest on the observatories of Spanish America.

THE account of the work of the Port Erin Biological Station given by Prof. W. A. Herdman to the Liverpool Biological Society on November 11 shows that the station continues to develop. It is expected that the much needed extensions now in progress will be completed and equipped by Easter of next year. During last summer vacation Prof. Herdman, Dr. Dakin, and Dr. Roaf conducted, for the first time, a valuable course of work in the science of oceanography (including hydrography and planktology). The work consisted partly of lectures and demonstrations in the biological station, partly of collecting and observing work on the seashore, and partly of expeditions at sea in the steam yacht *Ladybird* and in the Lancashire Sea Fisheries steamer. The operations of the fish hatchery at the station have resulted in the hatching and setting free at sea of upwards of 8,000,000 plaice fry and more than 5000 lobster larvæ—a substantial advance upon the work of any previous year. Plankton observations were carried out on the same lines as in the previous three years, three collections being made twice a week in the sea off Port Erin the whole year round. During July Prof. Herdman

took a series of vertical plankton hauls from various deep localities off the west coast of Scotland. A comparison of the collections show (1) that there is a constancy year after year in the nature of the plankton at certain localities, and (2) that some of the localities, not very far apart, differ considerably from one another in the nature of their plankton at the same time of year (July).

THE general committee of the Mansion House fund for providing a memorial to King Edward in London has had under consideration numerous proposals as to the form the memorial should take. The only decision which has as yet been arrived at is that, apart from the provision of a larger memorial of his Majesty, a statue of King Edward VII., with suitable accessories, be erected in some prominent and appropriate position in London, and that a fund be immediately opened for the purpose. Other schemes are still under consideration. Originally 164 proposals were received by the committee, but, according to the daily papers, these have been ruled out, with a few exceptions, as unsuitable or impracticable. The general committee has still to decide finally; but among schemes recommended to them by the executive committee are Lord Esher's proposal for an historical museum in London on the lines of the Musée Carnavalet in Paris. Secondly, the scheme of Lord Avebury for the building of a great hall for the University of London, to be used for degree and ceremonial purposes, and also for examinations. Thirdly, Lord Northcote's suggestion that a portion of the fund should be devoted to a scheme "for the protection of human life in the tropics by a great extension of that campaign against tropical disease which has already abated so largely the sum of human suffering." This last proposal has the support of the Society of Tropical Medicine and Hygiene, and a letter, signed by Prof. Ronald Ross, F.R.S., and other officers of the society, outlining the valuable work for the Empire which could be done by such an endowment of the study and prevention of tropical diseases, appeared in the *Times* of November 5. Lord Rosebery, as Chancellor of London University, has, in a letter to Lord Avebury, expressed his hearty approval of the scheme put forward by Lord Avebury.

ON November 8 Major Sykes delivered an interesting lecture to the Royal Geographical Society describing two short journeys which he took recently in north-eastern Persia the ancient Parthia, and Hyrcania. This district has always been one of special interest to the historian. It formed part of the patrimony of the earliest Persian kings; in it originated both the religion of Zoroaster and the Parthian dynasty, which measured its strength successfully with Rome; it has always been the debatable land on the border between Iran and Turan; and now it seems within measurable distance of falling, finally, into the possession of Russia, without any of the clamour, nay, danger, of war which such an advance of the Muscovite would have caused in England a few years ago. Such are the ways of high politics. The cities of north-eastern Persia are interesting also. Meshhed is a great centre of caravan-routes; ancient Nishapur is renowned as the birthplace and abiding-place of Omar Khayyâm; Turshiz is the traditional town of Zoroaster, where the great prophet converted Vishtâspa the king and planted the sacred cypress; Budjurd and Astrabad are interesting as really Turanian rather than Iranian towns. The dividing line between Hyrcania and Parthia was never drawn definitely. In the inscription of Darius the Great at Bisitûn (Behistun), the lands of "Parthva and Varkana" are mentioned together. The name of Hyrcania (Varkana) survives in that of the modern river Gurgân. Major Sykes had previously visited the valley of the Atrek, in which Budjurd lies. His route on this journey was taken from Meshhed to Budjurd, thence to Astrabad, and back by way of Shahrud, Subzawar, and Nishapur (the well-known old trade-route) to Meshhed. On the way he made several interesting explorations, and identified some ancient sites, notably that of Paras, which is probably the ancient Parthian capital. On his second journey he went to Nishapur and Turshiz. At Nishapur he identified the sites of several ancient cities which have been built near the spot from the original Niv-Shapur of Sapor I. to the mediæval Nishapur of Omar Khayyâm and the entirely different modern town. At Turshiz Major Sykes also made interesting discoveries.

IN spite of having presented his unrivalled collection to the nation, Lord Walsingham, as evident from a paper on Madeiran Tinerinæ in the November number of the *Entomologist's Monthly Magazine*, continues to devote attention to his favourite Micro-Lepidoptera. Two new species are described in this communication.

WITHERBY'S *British Birds* for November contains a long list of birds marked in the British Isles which have been recently recovered in various places, either at home or abroad. Among the items may be noted a teal marked in Essex in February and taken off Schleswig in August, and a tern ringed in Cumberland in July and captured south of Oporto in September.

IN a paper on the tooth-billed bower-bird (*Scenopœetes dentirostris*) published in the *Emu* for October Mr. S. W. Jackson states, as the result of continued observation, that, as a rule, during the height of the breeding season these birds do not visit their play-grounds or indulge in mimic vocalisation in the daytime, but reserve the latter performance for the periods before sunrise and after sunset, when they are in the tree-tops. During the nesting season the play-grounds are silent, unoccupied, and, most significant of all, untidy.

To the November number of *Pearson's Magazine* Mr. Walter Brett contributes an appreciative notice of the bird groups mounted in the Natural History Museum at New York. According to the author's own words, the birds in these groups "positively breathe with life. Their pose is natural; their surroundings are true to nature; their throats almost tremble with the song one expects to hear. And the reason of this is that these birds are life studies, scientifically correct as well as artistically perfect. The visitor knows they are stuffed only because he is aware that they are in a museum, not in an aviary." The article is illustrated with reproductions from photographs of several of the groups.

No. 1766 of the Proceedings of the U.S. National Museum is devoted to an account, by Miss Rathbun, of a collection of stalk-eyed crustaceans from the coast of Peru and adjacent parts of South America. The most notable additions to the fauna include a small crab of the genus Dromidia—the first of its group from western South America—and *Panopaeus bermudensis*, previously known from the Atlantic, while examples of two species hitherto represented by the types were also obtained. A noticeable feature is the abundance of Xanthidæ and Inachidæ and the scarcity of Parthenopidæ and shrimps of all kinds. Many of these Peruvian crustaceans, especially hermit-crabs, are used either as food or for bait.

AT the commencement of a review of the species of venomous toad-fishes of the genera Thalassophryne and Thalassothia, published as No. 1765 of the Proceedings of the U.S. National Museum, Messrs. Bean and Weed state that these fishes differ from all other members of the class by possessing grooved or perforated spines, analogous to

the fangs of venomous serpents, for introducing the poison they secrete into the bodies of their victims. In a specimen of *Thalassophryne reticulata* examined by the authors the poison-sac was found to occupy the whole length of the under side of the spine. The position of the sac is such that any pressure tending to drive the spine into the skin of another animal would produce a pressure on the sac, and thus inject the poison with considerable force into the wound.

THE ova and larvæ of teleostean fishes taken at Plymouth in the spring and summer of 1909 form the subject of the chief article in the Journal of the Marine Biological Association (October). The work was specially directed to practical questions connected with the fishing industry, such as the location of spawning areas, the duration of the spawning period, and the relative extent of the breeding of various kinds of fishes in the Plymouth area rather than to details of purely biological interest, and accordingly the descriptions of the eggs and larvæ forming the subject of the article bear special reference to the means of ready identification at different stages of development. A striking feature in the collection of pelagic eggs was the overwhelming preponderance of those of non-marketable species, such as rockling, rock-wrasse, boar-fish, and dragonets. It may be assumed, if sufficient samples be taken, that the relative abundance of eggs in the plankton affords a trustworthy index to the proportionate numbers of adult fish at the spawning season, and it may therefore be expected that in inshore areas such eggs should be largely those of rockling and wrasse. But this does not explain the predominance of dragonets, boar-fish, &c., over whitings, dabs, plaice, and soles. Although the latter are the objects of attention on the part of trawlers, it is still an open question to what extent the present state of affairs may be attributed to trawling.

IN the *Biologisches Centralblatt* (October 15) is published the first portion of an article, by Prof. K. Goebel, on sexual dimorphism in plants, discussing the extent to which diœcious plants are modified apart from the sexual organs. Examples of specific differences in seed plants are rare. *Cannabis sativa* is often quoted as a good example, although the author doubts if there is much distinction in a præfloral stage; he also questions whether it is possible to distinguish staminate and pistillate specimens of Cycas, Taxus, and Juniperus when not in flower. Amongst cryptogams better examples occur, notably in the case of such liverworts as *Symphyogyne leptothele*, which is figured. The fundamental reason for the differences lies in the necessity for providing more nourishment for the products of the egg cell, and this also explains the positions of the sexual organs in monœcious plants.

THE current number of *Tropical Life* (No. 9, vol. vi.) contains several articles on cotton cultivation both in the British Empire and the United States. In Egypt, Mr. Foaden points out, cotton occupies from one-half to one-third of the total acreage of cultivated land in those provinces where the conditions are suited to its growth, while the value of the crop is from 25,000,000*l*. to 30,000,000*l*. annually. Unfortunately, there has been a gradual fall in yield per acre during the past few years, the cause of which has been variously attributed to a rise in the subsoil water brought about by increased irrigation, to an increase in insect pests, and to soil exhaustion. Though the fertility of the Nile Valley is proverbial, the soils are usually deficient in nitrogen; crops show remarkable increases when nitrate of soda is applied or when a crop of clover—berseem—is ploughed in.

IN the current number of the *Fortnightly Review* Mr. J. Saxon Mills writes on the production of sugar from sugar beet, which he regards as one of the most hopeful schemes yet suggested for the benefit of rural districts. All the arguments in favour of the crop are set out concisely, and some very persuasive statistics are given. Field trials in Lincolnshire, Suffolk, Essex, and at Newnham Paddox have shown that crops varying from 15 to 20 tons per acre can be obtained containing 16 to 18 per cent. of sugar, while the Continental crops are lower both in quantity and in sugar content. Indeed, sugar beet is actually grown on a commercial scale in parts of the eastern counties, but is shipped to Holland to be worked up in the Dutch factories. It is contended that factories would prove highly advantageous in English country districts, and would also prove a remunerative investment. As several factories are already being started in England, it ought not to be long before very definite information is forthcoming on this question.

THE report on the Experiment Station, Tortola, Virgin Islands, for 1909–10, is to hand, and records certain improvements and additions to the station in connection with the sugar and cotton work and the water supply. The export trade in sweet potatoes and limes shows signs of increasing, while it has also been shown that a limited quantity of cacao could be produced for export. The cotton industry received a check owing partly to a fall in price and partly to bad weather; early planting is recommended as an improvement in cultivation. The report on the Botanic Station, Agricultural School and Experimental Plots, St. Lucia, 1909–10, shows that continued and steady progress is being made. During the year no fewer than 77,557 plants were sent out for distribution from the station, against 43,492 for the previous year. A scheme for prize-holdings competitions has been introduced, and will, it is hoped, raise the general level of cultivation.

IN a paper read at the November evening meeting of the Pharmaceutical Society, Prof. H. G. Greenish and Miss D. M. Braithwaite described a method by which the presence of the drug-room beetle (*Sitodrepa panicea*) may be readily detected in powdered drugs. The quantity of beetle present in an infested drug is so small that its direct examination under the microscope is practically impossible, and it is therefore necessary to separate the particles of insect from the drug before they can be observed. The process of separation devised by the authors is dependent upon the fact that the hardened parts of the mature beetle are of such a highly chitinous character and so extremely resistant to the action of acids, alkalies, and oxidising mixtures that it is possible to destroy the organic matter of the powdered drug without destroying the beetle. It is possible by means of the process described to detect particles of beetle in a powdered drug containing 0·00001 gm. of beetle in 5 gms. of powder. By the use of this method it can be shown whether a powdered drug is prepared from "worm-eaten" or sound material. In the course of their investigations the authors found that while the larvæ of the beetles undoubtedly ingest considerable quantities of starch, only a small proportion of this appears to be digested. It seems probable that the substances chiefly utilised as nutriment by the larvæ are not carbohydrates, but nitrogenous substances, such as the remains of protoplasm, &c.

BLACKHEAD is a highly infectious disease of turkeys prevalent wherever they are domesticated, and causes great financial loss each year. The symptoms are voluntary isolation, stupor, loss of appetite, drooping of the wings,

and emaciation; the disease is characterised by pathological changes in the cæca, intestines, and liver, while there are invariably present in the organs encysted stages of a coccidium, and also an amœba known as *A. meleagridis*. In a long Bulletin issued by the Agricultural Experiment Station of the Rhode Island State College Drs. Cole and Hadley give a detailed summary of the work so far done on the disease, and add a number of observations of their own. Although but little advance is recorded in the methods of prevention and treatment, the bulletin will be found very useful to those interested in diseases of birds, both by reason of its completeness and for the evidence it offers that the cause is a coccidium.

THE United States laws dealing with commercial fertilisers go further than our own in that they require the name of the firm to be published along with the analytical data dealing with the manures and feeding-stuffs supplied. Bulletin 141 of the Purdue University Agricultural Experiment Station gives the results of analysis of several hundred fertilisers and feeding-stuffs, together with the guarantee and the name and address of the manufacturer. Any case of fraud is thus at once exposed. The law is fully explained in the bulletin, and several illustrative cases are quoted. There are also tables showing the average composition of normal feeding-stuffs, and of the materials used as adulterants. Altogether, the bulletin gives a very good idea of the work of an agricultural analyst in the United States. A smaller bulletin on the same lines is sent us by the West Virginia University Agricultural Experiment Station.

IN one of a series of papers on the foraminifera of the shore-sands of Selsey Bill, Sussex, Messrs. E. Heron-Allen and A. Earland have described the forms derived from Cretaceous sources (Journ. R. Microscopical Soc., 1910, p. 401). In all cases these have been compared with specimens obtained from the hollows of flints in the same deposits; 118 species are identified, some of which are new to the records from the Upper Chalk. Mr. Heron-Allen offers a copy of a privately issued paper on Chalk foraminifera, printed in 1894, to any worker who may apply for it (address: Large Acres, Selsey). This earlier paper contains complete directions as to preparing material from the Chalk, as well as records of a number of species found at Twyford, many of which were previously known only in Cainozoic strata. It is pleasant to see that the veteran Mr. Joseph Wright, of Belfast, remains an active adviser on the work published in 1910.

COPIES have reached us of the valuable meteorological charts of the North Atlantic and North Pacific Oceans for December, and of the South Atlantic and South Pacific for the season December, 1910 to February, 1911, issued by the U.S. Weather Bureau. In the North Atlantic chart Prof. Moore continues the useful practice of exhibiting, by daily synoptic weather charts, specimens of the typical cyclonic storms which occur in that month. One of these disturbances, which was central near the Azores on December 18, 1909, moved quickly across Great Britain to the North Sea. The synchronous chart of December 21 shows that another storm dominated the entire northern part of the ocean, that typical cyclonic circulation prevailed from the American to the European continent, and that its disturbing influence was felt so far south as Madeira.

AN interesting application of the dilatometric method to the study of the polymorphism of the alkali nitrates is described by Prof. Bellati and Dr. Tinazzi in the *Atti del Reale Istituto Veneto*. It is shown that ammonium nitrate undergoes an abrupt expansion at 35°, a contraction at 86°, and a second expansion at 125°, corresponding with the three transition-points of the four modifications of the nitrate. Potassium nitrate undergoes an abrupt expansion at 127°, rubidium nitrate at 161°, cæsium nitrate at 148°, and thallium nitrate at 73° and 142° C.

IN reference to Dr. Baker's remarks on the Theory of Numbers at the Sheffield meeting of the British Association (NATURE, October 20, p. 514), Dr. Vacca, of Genoa, sends us the following quotation from Euler (Nov. Comm. Petr., vol. xvii., 1772, p. 25):—

"Non dubito fore plerosque, qui mirabuntur, me in huiusmodi questionibus evolvendis, quas nunc quidem summi geometrae aversari videntur, operam consumere; verum equidem fateri cogor, me ex huiusmodi investigationibus tantumdem fere voluptatis capere, quam ex profundissimis geometriae sublimioris speculationibus. Ac si plurimum studii et laboris impendi in quaestionibus gravioribus evolvendis, huiusmodi variatio argumenti quamdam mihi haud ingratam delectationem affere solet."

WE learn from the *Engineer* for November 11 that the Metropolitan Water Board intend to instal a battery of Humphrey gas pumps for the reservoir which is being constructed in the Lea Valley, near Chingford. A total pumping capacity of not fewer than 180 millions of gallons in twenty-four hours is required, made up of one unit of 20 and four units each of 40 million of gallons. It is understood that the Pump and Power Company, Ltd., offered to supply and erect on foundations provided by the Board five pumps of these capacities, together with a Dowson producer gas plant and all accessories, including two electrically driven compressors for starting purposes, for the sum of 19,388*l*. The guaranteed fuel consumption is not to exceed 1·1 lb. of anthracite coal fed into the producers per actual horse-power hour when working at the normal full load during an official trial of six hours' duration. The head to be pumped against is 29 to 30 feet, including friction. Thus a power of about 250 pump horse-power is required in each of the larger units. The conditions are ideal for the Humphrey gas pump, but as the power is larger than anything yet attempted by Mr. Humphrey, the results of the experiment will be awaited with considerable interest. At any rate, the Water Board cannot be accused of being behind the times.

AN article in the *Builder* for November 12 deals with a novel type of timber construction evolved by Mr. Otto Hetzer, of Weinar. In this new method the cross-sections of timber beams are adapted to actual stresses as in the case of riveted iron structures, and this is carried out by means of a composite beam with variable cross-sections in each given portion. A special glue being required, capable of forming an inseparable whole out of a number of composite parts, Mr. Hetzer seems to have succeeded, after many years of work, in producing one which possesses the required rapidity of binding, resistance against atmospheric influences, and the property of increasing hardening. The Hetzer compound beams are composed of three longitudinal layers, the uppermost of which is a wood characterised by a particularly high compressive strength (such as red beech), and the lowermost of a wood of great tractive strength (such as pine); the central portion need not be of any specially resisting material. An upward parabolic curvature is imparted to the central wood, so that in the central cross-section, submitted to the highest stresses, the whole of the deflection thrust is dealt with by this parabolic core and the lowermost layer. Satisfactory tests of these beams have been made at the Institute of Charlotten-

burg. Photographs of a bridge and several large roofs constructed under Hetzer's system are included in the article.

One of the chapters in the latest volume of "The Cambridge Modern History" (to be published on December 8), dealing with "The Scientific Age," is written by Mr. W. C. D. Whetham, F.R.S., who has undertaken the important and difficult task of surveying the trend of modern science in all its various departments. In this chapter will be found considerations of the Darwinian hypothesis, of evolution and religion, of electrical invention, of bacteriological treatment of disease, and other phases of modern scientific progress.

The October issue of *The Central*, the organ of the Old Students' Association of the City and Guilds of London Central Technical College, maintains the high standard previously reached by this periodical. The number is well illustrated, the frontispiece being an excellently reproduced portrait of Prof. W. J. Pope, F.R.S. Among articles contained in this issue may be mentioned those by Mr. H. Clifford Armstrong on steel making; Messrs. W. Gore and D. Halton Thomson on rainfall, steam-flow, evaporation, and reservoir capacity; Mr. Howard Mayes on boiler management; and Mr. A. G. T. Glaisby on birds and photography.

OUR ASTRONOMICAL COLUMN.

Discovery of a Comet.—A telegram from the Kiel Centralstelle announces the discovery of a new comet by Dr. Cerulli on November 9. Its position at 8h. 20·8m. (Rome M.T.) was R.A.=3h. 38m. 36s., dec.=8° 43′ 20″ N., and its daily motion amounted to −8s., −19′. The magnitude is given as 10·2, and the comet's position lays about half-way between, but slightly below the line joining, ζ and λ Tauri.

Metcalf's Comet (1910*b*).—Dr. Ebell publishes a continuation of his ephemeris for comet 1910*b* in No. 4452 of the *Astronomische Nachrichten*. This ephemeris covers the period November 13 to January 4, and shows that the comet is now moving slowly, in a north-easterly direction, through Serpens towards Corona; on December 8 it will be about ½° north of δ Coronæ, and of the twelfth magnitude.

Recent Fireballs.—A large number of fireballs have been observed during the last few weeks. The records of their appearance are not, however, sufficiently full and accurate to enable their real paths to be computed except in the cases where the objects were seen by capable observers.

The majority of the brilliant meteors have evidently belonged to a shower of Taurids, which is often very active in the first half of November, and is notable for the magnitude and conspicuous aspect of its members.

At 10h. 24m., November 9, one of the most interesting of the fine meteors recently seen was not a Taurid, but directed from a radiant at 312°+11° in the western sky. It passed from over a point east of Yeovil to west of Horsham at heights of 62 to 32 miles. The motion was unusually slow, viz. about 12 miles per second. The meteor sailed through the air in an apparently serpentine course, its sluggish, wriggling flight being specially noticed by observers at Bristol and other places, who mention it as quite an exceptional feature. There is no known shower at 312°+11° in November, but on November 2, 1801, Mr. Denning recorded a brilliant meteor close to its radiant, estimated at 311°+11°.

Solar Activity and Terrestrial Temperatures.—An important paper on the effect of solar changes on terrestrial temperatures is published by Mr. W. J. Humphreys in No. 2, vol. xxxii., of the *Astrophysical Journal*.

Mr. Humphreys accepts the interrelation of magnetic, and auroral, disturbances and sun-spot changes as established, and points out that terrestrial temperatures and rainfall are observed with sufficient accuracy to justify an examination of their relation to solar activity. Further, he considers rainfall dependent upon temperature, which is more accurately measurable, and so considers only the latter.

Taking Abbot and Fowle's conclusion that sun-spot maxima are accompanied by terrestrial temperature minima, and *vice versa*, the average range being 1° C., he points out the practical importance of a fuller knowledge of the nexus between these phenomena.

His conclusions, stated briefly, are that at spot maxima the solar atmosphere is more fully charged with "dust" (*i.e.* any particles capable of reflecting and scattering light), and therefore, owing to selective absorption, the proportion of ultra-violet radiations finally escaping will be diminished. Ultra-violet radiations acting on cold, dry oxygen, such as exists in the earth's upper atmosphere, produce ozone, therefore at spot maxima the amount of ozone will be less.

Further, it has been shown that ozone absorbs a much greater proportion of the earth-reflected radiations than of the incident solar radiations. Thus at spot maxima, with less ozone, more heat will escape, and a lower temperature ensue; the converse explains the observed rise of temperature at spot minima.

This process is complicated by many factors, such as the increase of ozone-producing auroræ at spot maxima, but Mr. Humphreys suggests that the observed change in terrestrial temperatures may depend largely, if not wholly, upon the selective absorption of the direct solar and the terrestrially reflected thermal radiations by the changeable amount of ozone in our upper atmosphere.

Stars having Peculiar Spectra, and New Variable Stars.—Circulars 158 and 159 of the Harvard College Observatory contains lists of newly discovered variable stars and stars having peculiar spectra. In No. 158 thirty-eight new variables, chiefly discovered by Mrs. Fleming, are tabulated, and there is also a list giving the positions, magnitudes, &c., of nineteen stars of which the spectra exhibit various peculiarities. Ten of these are of type vi., three are of type v. with bright lines, four are gaseous nebulæ, and in the remaining two Hβ is bright. In the spectrum of the ninth-magnitude star DM.−14° 5265 the bright line appears to be of slightly greater wave-length than Hβ, but is not the 5007 nebula line, and on a later photograph there is a trace of a bright line on the less refrangible edge of the dark Hβ; it is suggested that in this spectrum the bright line may be variable.

No. 159 contains a list of fifteen new variables discovered on Nos. 7, 10, 16, and 19 of the Harvard Map, and the usual analytical table shows that 0·41 of the probable variables on map 19 yet remain to be discovered. It is also stated that the very red star +46° 1817 apparently varies very irregularly.

The Discovery of Neptune.—No. 1954 of *La Nature* contains the complete text of the letter in which Leverrier sent to Dr. Galle the results which led to the visual discovery of Neptune. It is stated that the first time the whole of this historic document has been published is in a recent article by Dr. See in *Popular Astronomy*, and it is suggested that the proper place for the original would be in the museum of the Paris Observatory.

Variable Stars in the Orion Nebula.—No. 4451 of the *Astronomische Nachrichten* contains a list of eleven more stars, in the nebula of Orion, which are apparently variable. The number of known variables in this nebula now amounts to 156.

THE BANQUET TO JUBILEE PAST-PRESIDENTS OF THE CHEMICAL SOCIETY.

The council and fellows of the Chemical Society honoured five of their past-presidents who had completed their jubilee as fellows by entertaining them at a banquet at the Savoy Hotel on Friday, November 11. A large gathering numbering 250, including the Duke of Northumberland, the Postmaster-General, the presidents of the French and German Chemical Societies, and no fewer than eleven past-presidents, was presided over by Prof. Harold B. Dixon, F.R.S., the president.

The names of the past-presidents who were being honoured were:—

	Elected	President
Prof. William Odling, F.R.S. ...	1848	1873–5
The Rt. Hon. Sir Henry E. Roscoe, F.R.S.	1855	1880–2
Sir William Crookes, O.M., F.R.S.	1857	1887–9
Dr. Hugo Müller, F.R.S. ...	1859	1885–7
Dr. A. G. Vernon Harcourt, F.R.S.	1859	1895–7

Unfortunately, Sir Henry Roscoe was absent through illness.

After the loyal toasts had been duly honoured, the president gave that of the "Past-presidents who have completed their Jubilee of Fellowship." He referred to the personalities of the jubilee past-presidents, and to the particular work in which each was more especially distinguished: Sir Henry Roscoe, for his research on vanadium and as a pioneer educationist; Sir William Crookes, for his discovery of thallium, his researches on the rare earths, the genesis of matter and diamonds, and his brilliant discoveries in physics; Dr. Hugo Müller, for his researches on cellulose and discoveries in connection with printing; Dr. Vernon Harcourt, for his researches on the rate of chemical change and his work as an enthusiastic teacher; and Prof. William Odling, the doyen of chemistry, to whom all chemists will find it difficult to fathom their debt of gratitude.

In replying to the toast, Sir Henry Roscoe, whose speech was read by the president, drew on his reminiscences of the thirty-one past-presidents of the society, all of whom with the exception of two he had known, and of his association with the society.

Sir William Crookes sketched the steps by which he was led to the discovery of radio-activity. He stated that no law is more certain than the law of change. Radium has shaken our belief in the conservation of substance, the stability of the chemical elements, the undulatory theory of light, and the nature of electricity; it has revived the dreams of alchemists, and has cast doubt upon the very existence of matter itself. Physicists are beginning to say that there is no such thing as matter; that when we have caught and tamed the elusive atom and have split it into 700 little bits these residual particles will turn out to be nothing more than superimposed layers of positive and negative electricity. Speaking of the War Office Committee of which he was a member, he stated that what our country now most urgently requires is "brain-craft," the master of "hand-craft," and researchers who will cultivate chemistry for its own sake.

Dr. Müller commented on his association with the Chemical Society, on its rapid growth and increasing activity.

Dr. Harcourt referred to the influence of the growth of chemistry upon the teaching of the science as a part of general education, and to the importance in education of a knowledge of the general results of scientific inquiry and of some insight into the methods by which such knowledge has been gained. He mentioned the difficulty which the teacher of chemistry finds in keeping himself abreast of his subject, and the danger of teaching the latest hypotheses to students who are only studying science as a part of education and chemistry as a part of science, if it mislead them into believing that, because they have gained the latest lights, they have a thorough grasp of the science.

Prof. Odling referred to his connection with the four past-presidents who, with him, were being entertained, and with many of the older chemists, and of the association of Oxford University with the society.

Sir Edward Thorpe proposed the toast of the honorary and foreign members, which was replied to by Prof. Haller, president of the French Chemical Society, and Prof. Wallach, president of the German Chemical Society. At the conclusion of his speech Prof. Haller presented, on behalf of his society, a silver medal of Lavoisier to each of the jubilee presidents in honour of the occasion.

The last toast of the evening, that of "The Guests," was prooosed by Sir William Tilden and acknowledged by the Duke of Northumberland, president of the Royal Institution of Great Britain, Mr. H. L. Samuel, the Postmaster-General, and Herr Generaldirektor S. Eyde, of Christiania.

THE INTERNATIONAL AGROGEOLOGICAL CONGRESS AT STOCKHOLM.

A FEW months ago (August 4) we reviewed the proceedings of the first International Agrogeological Congress, held at Budapest in 1909. The second was held this year simultaneously with the International Geological Congress at Stockholm, as an experiment. It was well organised by the local committee and well attended, the membership numbering about 160. The sessions were arranged to allow the frequent attendance of members at the geological meetings in which they were likely to be interested. But it seems to have been recognised by most that the bonds of association between the two congresses were not so close as to render it necessary, or even desirable, that they should be held at the same place and time; and it was decided by the council that the next meeting should take place independently at St. Petersburg four years hence.

A prominent feature in connection with the congress was the very interesting exhibition of specimens, maps and instruments illustrating the science of the soil, which was brought together in the rooms of the Technical School, 44 Mästersamuelsgatan. The Swedish exhibits, which naturally formed the greater part of this collection, included sample-sections of the typical soils and subsoils down to the underlying strata from which they were derived. The sections of peat-mosses which showed changing conditions of accumulation were particularly noteworthy. Excursions were made, both during and after the congress, through selected districts and to the chief agricultural stations, thus enabling the visitors to appreciate the local methods of practical research, as well as to gain personal knowledge of Swedish agricultural conditions.

The papers read at the meetings were grouped together by their subject-matter, so that each session was devoted to the discussion of a separate problem. As was to be expected from the earnestness which has been thrown into the study of soils in Germany, most of the papers were given in German. Indeed, hardly any other language was used at the sessions. At the opening meeting on the morning of August 17, Prof. Gunnar Andersson delivered his instructive presidential address on "The Swedish soil-types and their distribution," in which the geological bearings of the soil-study were allowed a prominence which they rarely attained in the subsequent discussions. At the afternoon session the 'leit-motif' was "The mechanical analysis of soils," with illustrative papers by Dr. A. Atterberg (Sweden), Prof. P. Vinassa de Regny (Italy), and Dr. W. Beam (Egypt).

At the subsequent sessions, on August 18, 19, 20, 22, and 24, the following were the principal subjects of discussion:—"Colloids of the soil," introduced by papers by Prof. E. Ramann (Germany) and Dr. D. J. Hissink (Holland); "Preparation of extracts of soils for chemical analyses," after papers by Prof. A. de Sigmond (Hungary), Prof. A. Vesterberg (Sweden), and Prof. A. Rindell (Finland); "Nomenclature and classification of soils," with papers by Prof. E. W. Hilgard and Prof. R. H. Loughbridge (California), Prof. P. Kossowitsch (Russia), M. Béla de Inkey (Hungary), and Dr. B. Frosterus (Finland); "Systematic soil-surveying," with papers by Dr. K. O. Björlykke (Norway), Prof. K. Gorjanovič-Kramberger (Croatia), and Prof. F. Sandor (Croatia); "The analyses of peat soils," with papers by Dr. E. Haglund (Sweden) and Dr. H. von Feilitzen (Sweden). There were a few other papers, chiefly on the chemical side of the subject, which did not fall under the above headings, among them being an interesting general account of the soils of Egypt, by Dr. W. Fraser Hume.

As a merely personal impression of the proceedings from a geologist's point of view, it may be remarked that, with the rapid advance of specialisation in the study of soils, the connection of the subject with geology seems to have become more remote. It was only in the papers dealing with the mapping of soils that geological considerations were brought into prominence, and even then only as a basis for specialised classification. For the rest, it was toward physics, chemistry and plant-physiology that the new methods of research approximated. The major part of the papers dealt with the laboratory treatment of soils, mechanically and chemically, and with the

resultants of the varied treatments. In the process of dismemberment it must often happen that the true individuality of a soil is lost, so that schemes of laboratory classification sometimes arbitrarily separate agricultural similars and unite agricultural discordants. This was recognised in several of the discussions, and the students of the soil are now fully alive to the complexity of the problems needing investigation. In the opportunity afforded for comparing and criticising the diverse methods of research the congress was eminently successful; and on the social side it was wholly pleasurable.

EDUCATION AT THE BRITISH ASSOCIATION.

The presidential address this year was devoted to the topic of university education. Readers of Nature have already had an opportunity of reading Principal Miers's suggestive discussion of the relations of teachers and pupils at school, and of the change of method which should differentiate university from school education. Incidentally, the address raised the very practical question of the present overlapping of the two, and led to the appointment of a research committee, with the president as chairman, to investigate the subject and to report at Portsmouth next year.

The presentation of the reports of the Section L research committee on mental and physical factors involved in education, and of the committee of Section H on the establishment of a system of measuring mental characters, was made the occasion for a joint session of the two sections for the discussion of research in education. In the report of the committee of Section L the gradual integration of a science of education, drawing its data, as Prof. Schuyten wrote, from hygiene, anthropology, physiology, normal and abnormal psychology, pedagogy, and sociology, and yet with a common centre of reference and an inner coherence which set it apart from each of these related sciences, was indicated. The work in psychopedagogy now carried on in this country was briefly reviewed, and it was shown that, in spite of the lack of funds which was everywhere reported, researches were on foot in at least ten university centres. Prof. Green in his introductory remarks showed how poorly off we are in this respect in comparison with such countries as Belgium, France, Germany, the United States, and even with Russia, where the War Office, in discharging its responsibility for the education of the children of officers, maintains a professor and a laboratory for research work alone. He also urged the importance of training for researchers in this as in all other branches of specialised research, a point which was subsequently taken up by Dr. C. S. Myers and other speakers. Prof. Findlay explained how the university departments were in this matter sent from pillar to post, Treasury grants being refused on the ground that the Board of Education always looked well after their own, while the Board, on the other hand, in set terms disavowed all responsibility for research work. The position, as the president said, is "disgraceful."

A typical illustration of more purely pedagogical research was contributed by Dr. T. P. Nunn in his sketch of the methods of algebra teaching worked out in the demonstration schools attached to the London Day Training College. The old theory of algebra, associated with the name of Euler, in which the symbols are regarded merely as numbers—"a large number of numbers"—has given place to the view of Chrystal and others, to whom algebra is a systematic science capable of development from its own axioms. The difficulty of adopting this view for school purposes is precisely the difficulty which faces the new school of geography teachers, namely, that the rationalising motive, the desire to build up a system for its own sake, does not develop in the English schoolboy much before his sixteenth or seventeenth year. Dr. Nunn has therefore based his method on the utilitarian motive, and aims at every stage to exhibit the value of the results for application. At the same time he seeks to comply with the schoolmaster's demand that the subject shall have "training value." Thus algebra for school purposes becomes an instrument the capabilities of which are throughout explored, and so extended, a kind of linguistic for the expression of thought operations. A large audience followed with keen interest Dr. Nunn's application of the theory in such crucial instances as the factorisation of a^2-b^2, and the explanation of the product of two negatives. The processes under his hand revealed the behaviour of realities, and no longer, as of old, came out of the void.

As an illustration of research upon mental processes Dr. Spearman gave an account of an inquiry into individual variations of memory among some 400 subjects. His results showed that the correlation coefficient between different ways of memorising was always positive, or, in other words, that the powers of memory showed some tendency to correspond, however the material upon which they were exercised might vary, while the more like two performances were the greater was the degree of correspondence. The common view that people of quick memory forget more rapidly than those to whom memorising is a slow process was shown to be erroneous, the correlation coefficient between the two remaining the same after a lapse of time. It was also shown that the difference between the two types could be largely traced to the method of recall, the quick memory being predominantly auditory and motor, the retentive memory visual and ideal. Finally, a high correlation was established between memory and teachers' estimates of general intelligence, in spite of the fact that the data upon which the latter were based were often obscure and variable.

The remainder of the sitting was occupied by a series of papers and discussions on the measurement of intelligence, in which accounts were given of practically all the researches on this subject hitherto conducted in this country. Dr. Otto Lipmann discussed the methods of Binet and Simon (*Année Psychologique*, 1908, xiv., pp. 1–94) and of Bobertag (*Zeitschrift für angewandte Psychologie*, iv.). His paper has been printed in full in *The School World* (October), so that here it will suffice to say that in his opinion their methods do not promise any certain test of a high degree of intelligence. We associate intelligence of this character with depth and power of self-criticism; but these things must be neglected in experimental tests, for results which would demonstrate the absence of these may be due to bodily condition or temporary inattention. On the other hand, the tests of Binet and Simon will establish with certainty whether a child is of sufficiently normal intelligence to be equal to the public-school course. The importance of this achievement will be seen when it is remembered that under English law a school medical officer may at any moment find it necessary to satisfy a bench of magistrates that a particular child ought to be sent to a special school for mentally defective children.

Mr. Cyril Burt described a series of experiments performed with a group of elementary-school children at Oxford, the result of which was to cast doubt upon the view that there is an intimate correspondence between power of sensory discrimination and general intelligence. A series of experiments with girls of secondary-school age at Liverpool tended to show that, by comparison with simple sensory and motor tests, tasks involving higher and more complex processes are less liable to be vitiated by absence of special training in the experimenter, and also have a more intimate relation with intelligence. Mr. William Brown discussed the mathematical technique of the evaluation of the results of intelligence tests, and maintained that the method of multiple correlation should always be employed.

Mr. J. G. Gray asserted the value of perseveration as an index of the quality of intelligence, explaining perseveration as dependent upon an elemental brain property which determines the persistence of mental impressions. He described a modification of Wiersma's colour disc devised by himself in order that the luminosity of the two colours the fusion of which at a certain rotation speed gives the index of perseveration might be regulated by the experimenter.

Mr. H. S. Lawson described a series of tests, based upon Binet's, to which the candidates for scholarships at a Midland secondary school were submitted. The order thus established was correlated with the official scholarship order in two successive years, the coefficients being 0·217 and 0·485. The tests had also been used to check the official order of merit obtained from a term's marks

in certain forms. In every case the correlation coefficient was high.

Miss Katharine L. Johnson read an interesting paper on the results of the application of Binet's tests to 200 schoolgirls in Sheffield. In her experience one of the chief difficulties was the personal equation of the experimenter. It is impossible to maintain the same tone and expression throughout, and children are very susceptible to suggestion. It is also difficult, sometimes, to estimate the results. She had found cases in which girls failed in the tests for their own age or for the age preceding, and yet satisfied the tests for a superior age.

Dr. E. Neumann's paper was summarised by Dr. Lucy Hoesch Ernst. He cast a doubt upon the possibility of determining a normal standard of intelligence for each year of school life which would be of general validity because of the difficulty of excluding acquired knowledge.

Dr. C. S. Myers entered a caveat against the collection of masses of psychological data by untrained observers. He was of opinion that the personal equation of the observer could not be got rid of, and that therefore comparison of results was only possible within very narrow limits. Racial differences in correlation are bound to vitiate the results of the examination of a sample of a heterogeneous people. But the main source of error lies in the neglect of the introspective element. A test of mental fatigue may in different subjects involve the play of such complicating factors as boredom, duty, ambition. It is only by individual introspection that we can determine exactly what factors an experiment involves. The result derived from the wholesale collections made by untrained observers can be nothing but a blur in the psychological aspect, though a sort of standard of productiveness may be obtained from them whereby we can measure the individual.

Dr. W. H. R. Rivers summed up the long discussion. In his opinion the work done was well worth doing, and marked a great advance regarded from the point of view of the scientific psychologist. But an enormous amount would still have to be done before the results could be applied practically in education. The work, so far, had been work with mass results, whereas the teacher wanted to test the individual. In spite of what had been said of the need for training in the investigators, it was all to the good that teachers were beginning to take up psychopedagogy.

On the third day of the meeting there was a series of papers on practical work in schools. The Board of Education's recent Memorandum on Manual Instruction came in for a good deal of praise. Sir Philip Magnus, as an old fighter in the cause of handicraft, urged that we should not fold our hands until the Board's four principles were everywhere observed, that handwork should be taught to all intending teachers, and that there should be a continuous course of it in every school taken by the ordinary teachers of the school. The president of the association spoke of the value of handwork as fostering self-help and initiative. Mr. J. G. Legge suggested the establishment of a type of school for boys from twelve to fourteen in which half the curriculum should be given to constructive work, and half the day should be spent in the workshop. Such a school would lead directly to technical training as the next stage in the education of the pupils. Mr. James Tipping described the vacation courses of the Educational Handwork Association, in which many teachers have acquired the manipulative skill, and at the same time the pedagogical knowledge, needed by teachers of handicraft; and Dr. G. H. Woollatt outlined a hundred-hour course for teachers in the making of scientific apparatus. Miss Cleghorn, in closing the discussion, warned the audience that enthusiasm in the teacher was a *sine qua non*, and hinted, at the same time, that it was difficult to be enthusiastic over the introduction of more subjects into the too short school life of the ordinary child.

Mr. Blair's paper on the relations of science with commerce and industry has already appeared in NATURE (September 15). The subject is usually treated on both sides in a spirit of vague vituperation which profits nothing. Mr. Blair's skilful marshalling of a mass of evidence from university graduates, professors, business men, and manufacturers all the world over will be of service to combatants on both sides who desire composition and not strife. In the short discussion which followed Principal E. H. Griffiths advocated bringing home to the lay mind the value of such work as Faraday's and Lister's. We should then hear less of the disinclination to believe in the application of science to business life and industry. He also advised scientific men to leave the language of the laboratory behind them when they came into the market-place, recalling Sir George Reid's words in the tests of intelligence discussion:—"It will be a grand thing when our men of science really do know everything they talk about, because when they do they will be able to tell us what it all means in plain English."

Dr. Beilby thought that things were improving; the great need was more cooperation between the two parties. The difficulty was to get the scientific man and the men of the markets together. In joint committees of professors and business men each side educated the other.

Sir William White also thought that there was no reason for alarm. We did not compare so badly with other countries. True, our rivals were better organised, but then organisation may paralyse effort. The young trained graduate of the technical college would not straightway apply his knowledge in industry; he had not the knowledge of practical business conditions. Such men should go through post-graduate courses, if possible, in works' laboratories. We must be content to train many mediocrities in order to catch the man of brilliant ability, and fortunately it takes all sorts to make the worlds of commerce and of industry.

Dr. Stead said that in the steel industry the value of research was recognised. The manufacturers had reached the point of wanting a little too much from research, and in too short a time.

Dr. H. E. Armstrong also advocated a two or three years' course in a work's laboratory for the technical-school graduate, and quoted the example of Sir Lothian Bell. Our organisation was at fault; when that defect was remedied the nation would soon regain its former commanding position in manufacture and commerce.

On the last day of the meeting an interesting series of papers was read on outdoor studies in schools of normal type. Prof. Mark R. Wright described the summer camp of the Durham Training College, Mr. G. G. Lewis showed what could be done by means of school journeys for London elementary-school children, and Mr. J. E. Feasey explained how much the interest and practicability of ordinary school work could be heightened by adapting it to the conditions of the open air.

In the afternoon there was a lively, though inconclusive, debate on voice production, in which Dr. Gray, Prof. Wesley Mills, Dr. Hulbert, Mr. W. H. Griffiths, Miss Ormay, Dr. Chichele Nourse, Prof. Silvanus Thompson, and others took part.

THE PRODUCTION AND USE OF ELECTRIC POWER.[1]

THERE are few subjects more important to the people of this country than the question of the rapid and ever-growing rate at which we are using up our coal supplies. Many writers have dealt with this subject, and have suggested various remedies.

It may be said that the rate at which we can use coal is a measure of our industrial activity and prosperity. This would be true, perhaps, if we were using our coal without waste, or at least with reasonable economy, but it is certainly not true of what we are at present doing.

Taking all the uses for coal into consideration, I believe that we are getting back an amount represented by useful work of one kind or another of much less than 10 per cent. of the energy in the coal. We can never, of course, hope to get anything like the full value of the energy in the coal, but, on the other hand, throwing away more than 90 per cent. of the value of our coal in the process of conversion is of the greatest possible concern to the country. Moreover, there is a further waste involved in our present methods of using coal which is only second in importance to the one I have spoken of. We now dissipate nearly the whole of the valuable by-products con-

1 From the Inaugural Address delivered at the Institution of Electrical Engineers on November 10 by Mr. S. Z. de Ferranti.

tained in the coal, consisting principally of fixed nitrogen.

It is in the process of transformation of coal into work in the form of heat and power that the great loss occurs, as this is always a most difficult process, and requires the highest scientific and practical skill to carry out with even very moderate economy.

It has been proposed, with the view of accomplishing the above ends, to treat the coal at central stations and turn it into gas and distribute the energy in this form, but this process only goes a small way towards a solution of the problem, as under it combustion—which is such a difficult problem—would be taking place at numerous points over the whole country, all tending to inefficiency, and the conversion of the gas into power is by no means easy, involving running machinery of the reciprocating class, requiring special and skilled attendance.

It appears that with a problem such as we are discussing it is fundamental that the energy in the coal should be converted at as few centres as possible into a form in which it is most generally applicable to all purposes without exception, and in which it is most easily applied to all our wants, and is, at the same time, in a form in which it is most difficult to waste or use improperly.

We are therefore forced to the conclusion that the only complete and final solution of the question is to be obtained by the conversion of the whole of the coal which we use for heat and power into electricity, and the recovery of its by-products at a comparatively small number of great electricity-producing stations. All our wants in the way of light, power, heat, and chemical action would then be met by a supply of electricity distributed all over the country.

It must, however, be remembered that the distribution of energy in the form of electricity instead of coal can only be effectively carried out when it can be done in such a way that it is available for all the purposes for which coal is now used, and this can only be the case when the conversion is effected at such an efficiency as will cause the electric energy delivered to represent a high percentage of the energy in the coal. Failing this, no scheme for conversion at the pit's mouth and delivery of energy in the form of electricity is sound. There is also another controlling factor which must be satisfied in order to make this scheme possible. Both the conversion of the coal into electricity and the distribution of the current must be effected at a low capital cost, so as not to overburden the undertaking with capital charges.

Considering the various processes of conversion which are now available, or may be invented, and their possible and probable efficiency, we first come to electric generators driven by reciprocating steam engines. Their economy, expressed in the form of energy in the coal to electric energy, may be taken as a maximum of 10 to 12 per cent. This is, of course, far too low an efficiency to make any scheme such as I have already indicated possible, besides which the capital expenditure and the complication involved are far too great and the size of the units too small to be thought of for the purpose in view.

We next come to large steam turbines such as have been constructed up to the present, and see that their maximum efficiency may be put down at about 17 to 18 per cent.

Next in the list, in order of economy, comes the big gas engine fed from gas producers, with an efficiency of coal energy to electric energy of possibly 25 per cent.

In the future we have to look towards two other means of conversion—the gas-turbine-driven electric generator and the production of electricity in some more direct way from the coal; but these two means of conversion, although being capable of giving the most efficient results, are so much in the distance that they are quite beyond our present consideration.

After very careful thought on the subject I have come to the conclusion that, in order to supply electricity for all purposes, it would be necessary, amongst other things, to have a conversion efficiency of not less than 25 per cent.

For the purpose of looking into this question I have taken the figures of production and consumption given in the report of the Royal Commission on Coal, which clearly summarises the position as it stood a few years ago, and as the increase taking place is fairly regular these figures have been taken throughout. According to this report 167 million tons of coal were being used in the country in 1903. Of this amount 2 million tons went to coasting steamers and 15 million tons were used by the gas companies. In order to simplify matters and make the figures clear, I have left out of consideration the coal used on these two items, and taken the balance—viz. 150 million tons—as the annual coal consumption of the country. If now, instead of using this coal for doing work, as at present, we were to convert it into electricity, we should use, instead of 150 million tons, 60 million tons of coal a year. This coal, turned into electricity, would produce 131,400 million Board of Trade units, and the electricity so produced would, after allowing for losses of transmission and conversion into work of different kinds, be sufficient to supply the whole of our requirements now being satisfied by the use of the 150 million tons of coal which we now burn.

Summarising the whole position, it may safely be said that, wherever coal, gas, or power are now used, everything for which they are used will be better done when electricity is the medium of application.

Hardly less in importance in the all-electric scheme is the question of the by-products which become available by the proper use of our coal. These consist principally of fixed nitrogen, together with tar and oils.

Fixed nitrogen in the forms of sulphate of ammonia, nitrate of soda, and nitrate of lime are most valuable fertilisers, and enable land continually to produce the same crops with a greatly increased yield per acre. Much has been done in finding out how best to utilise these artificial fertilisers, but no doubt a great deal more will be done in this direction, and fertilisers will be prepared, with fixed nitrogen as their principal constituent, which best suit the particular soils and crops that it is desired to deal with.

According to last year's Board of Trade returns, we now grow about 23 per cent. of the total wheat that we use and import 77 per cent. Of the barley used we grow 59 per cent. and import 41 per cent., and of the oats used 78 per cent. is home grown and 22 per cent. imported. Last year we devoted $7\frac{3}{4}$ million acres to the cultivation of these crops.

Much is being done to improve the yield of corn crops, and it is probable that with scientific treatment in the production of the seed, in the sterilisation of the ground, and in the application of fertiliser, we may look at no distant date to an increased yield of 50 per cent. in these crops upon what is now being produced per acre. The most vital feature, however, in bringing this about, once we have acquired sufficient knowledge, is an ample supply of fixed nitrogen to use as fertiliser, and it is when considered from this point of view that a scheme which supplies this from our coal as the result of saving present waste is most important.

With the increased yields which we have mentioned we could produce corn crops sufficient to supply the whole of our requirements upon 11 million acres. This would represent $23\frac{1}{2}$ per cent. of our present cultivated area, and would only be an addition of $3\frac{1}{4}$ million acres to the land now used for the purpose of growing these same crops. The value of these additional crops would be about 58 millions sterling, based upon the prices which we paid last year, and to this would have to be added the value of the straw and the other wheat by-products, which would go a long way towards providing the food for growing the additional meat which we require to supply our demand at home.

In order to fertilise the land we should have available, under the all-electric scheme, 3 million tons, or its nitrogen equivalent, of sulphate of ammonia. This, if used over the whole of the $46\frac{3}{4}$ million acres now under cultivation, would give 143 lb. per acre; but, of course, the fertiliser would be distributed according to the nature of the land and the crops being grown. It is probable that in these circumstances the increased yield of the land now cultivated would not only give us all the grain that we should require for food, but also all the foodstuffs, partly as by-product from the grain and partly grown, that would be required for raising the cattle, sheep, and other animals necessary to supply the whole of our wants.

It is now beginning to be understood that intensive farming of the land also involves intensive cattle raising,

and that it is very advantageous greatly to reduce the amount of grass land and instead to grow crops intensively cultivated, as in this way a given amount of land can be made to produce a much larger yield.

Sulphate of ammonia is a particularly good fertiliser for the purpose of growing sugar beet, and here again it is probable that the availability of large quantities of this fertiliser at a very much lower price than at present prevails would enable us to produce the whole of our sugar at home, especially as the by-product, obtained in the form of crushings from the beet, is a very valuable food for cattle raising, and also as the crop is a very suitable one for growing alternately with wheat.

If it was found that a larger amount of fertiliser than the 3 million tons of sulphate of ammonia, which would be the principal by-product from 60 million tons of coal turned into electricity, could be advantageously used, this would be very economically produced from the electrical station by the oxidation of atmospheric nitrogen, giving a valuable fertiliser in the form of nitrate of lime. This could be made intermittently by means of current filling up the load curve, and would not necessitate the expenditure of any more money on plant for generation or transmission of the current. It would, however, require the burning of additional coal, and this in itself would add to the sulphate of ammonia available.

It is assumed by many people that the climate of this country is largely unsuitable for the purpose of growing food, and for this reason it is thought that we can never grow the food which we require. This is largely a misconception, as crops both large in quantity and of good quality can be produced in this country. Nevertheless, it would be a desirable thing if, instead of the dark weather that we now often experience owing to cloud obstruction, we could have continuous sunshine at certain times of the year. The amount of sunshine would, no doubt, be largely increased by the abolition of all smoke in the air, as not only does the smoke itself obscure the sun, but also it seems to have the effect of assisting the formation of cloud, which greatly diminishes the light and heat which we receive.

At present it is considered quite right and reasonable to canalise rivers and make great works for adding to the fertility of countries by means of irrigation, but I believe that in the future the time will come when it will be thought no more wonderful largely to control our weather than it is now thought wonderful to control the water after it has fallen on the land. I think that it will be possible to acquire knowledge which will enable us largely to control by electrical means the sunshine which reaches us, and, in a climate which usually has ample moisture in the atmosphere, to produce rainfall when and where we require it.

It seems to me that it may be possible, when we know a great deal more about electricity than we do to-day, to set up an electrical defence along our coasts by which we could cause the moisture in the clouds to fall in the form of rain, and so prevent these clouds drifting over the country between ourselves and the sun which they now blot out. It also seems to me that it will be possible, when more water on the country is required, to cause the falling of rain from the clouds passing over the highest part of the country, and so produce an abundance of water which, properly used, would greatly add to the fertility of the country.

Of course, it may seem that these are only mad visions of the future, but I think we can hardly consider these results more improbable than anyone would have considered wireless telegraphy or flight in heavier-than-air machines fifty years ago. My excuse for mentioning these matters here is that they might constitute another great use of electricity, and their useful consummation would certainly be facilitated by an abundant supply of electrical energy.

At present, although the using of our coal may mean commercial activity, it certainly means the desolation of the country in parts where it is largely used. Instead of this harm being done to the country by our coal, we should fertilise the lands by its means, and might even, as I have indicated, use it in the future to increase our sunshine.

Of course there are many things which at present stand in the way of realising such a scheme as I have outlined. There are many technical details which nothing but an immense amount of work can solve satisfactorily. There are also political and legislative difficulties standing in the way, but these, when the time arrived, would have to be got rid of rather than allow them to handicap the advance of the country. The more, however, that I have considered these ideas in detail, the more certain am I of the fundamental soundness underlying them, and that it is only a matter of time before such a scheme is carried out in its entirety.

What interests us most, perhaps, is the question of how long it is likely to be before the all-electric idea becomes possible. At present there is so much required to be done to make it workable in all its details that it seems as though its realisation would be long deferred. It must, however, be remembered that knowledge is continually being acquired which brings us nearer to its realisation, and that things engineering, and especially in electrical engineering, now move very rapidly. It may therefore come to pass that the all-electric idea, with its far-reaching changes and great benefits, will become an accomplished fact in the near future.

MATAVANU: A NEW VOLCANO IN SAVAII (GERMAN SAMOA).[1]

THOUGH not the seat of government, Savaii is the largest of the Samoan Islands in the Central Pacific Ocean. It has a backbone of volcanic mountains, some of which rise to a height of more than 4000 feet; most of them are extinct or dormant, but there have been several small eruptions within the last 200 years, and one as lately as 1902.

The volcano of Matavanu was formed in 1905 to the north of the main ridge, and near the centre of the island. The early part of the eruption was characterised by explosions, and the ejecta were mainly solid, but later on

FIG. 1.—Steam Clouds from Lava falling into the Sea.

[1] Abstract of a Discourse delivered at the Royal Institution on Friday, April 29, by Dr. Tempest Anderson.

an enormous quantity of very fluid basic lava has been discharged. This has flowed by a sinuous course of about ten miles into the sea, devastated some of the most fertile land in the island, and covered it up with lava fields probably not less than twenty square miles in area.

The crater contains a lake, or rather river, of molten lava so fluid that it rises in incandescent fountains, beats in waves on the walls, and rushes with great velocity down into a gulf or tunnel at one end of the crater. The lava, still liquid, runs in a passage, or perhaps system of passages, under the surface of the lava field, its course being traceable by a line of large fumaroles until, still in a fluid condition, it reaches the sea, into which it flows with energetic explosions and the discharge of large volumes of steam, black sand, and fragments of lava. Where the action is less violent a structure resembling that of some varieties of pillow lava is produced.

FIG. 2.—Pit Crater in Lava Field, on the line of the Lava Tunnel to the Sea.

Photo.] [*T. Anderson.*
FIG. 3.—Lava in Lagoon corded above high water-mark: Pillow Lava below.

The term pillow lava, originally applied to the results of a peculiar form of spheroidal weathering, is now extended to various smooth-surfaced lobular masses, which have been considered by Teall, Cole, and Gregory to be formed by lava flowing into water. This view has been combated by others; but Dr. Anderson watched the process actually going on, and photographed the results.

The formation of ordinary "corded lava" or "pahoehoe" takes place by a local quiet outflow of lava which forms a pool or lobe. The surface, being slowly cooled by the air, forms a more or less tenacious, treacly scum, which is pushed forward by the liquid mass underneath, and is puckered up into a cord or festoon. While this is taking place the new surface is becoming treacly, and in its turn is pushed forward into another fold, and so on until the whole surface is solidified, often with a very regular pattern.

Dr. Anderson said he had seen this taking place on Vesuvius, and had watched the same process going on at the sea-level at Matavanu. The surface of the lobes, however, being in that case exposed to the waves, was rapidly chilled, and solidified before it had time to be pushed forward to form "corded structure." A photograph of a recent flow into the lagoon showed corded structure above high-water mark, while lower down there was every transition into typical pillow lava.

The surface of the lava field shows several large pits along the line of the lava-conduit to the sea, out of which steam and vapours escape. They are larger than ordinary fumaroles, and appear to be formed by the remelting and falling in of the crust owing to the heat of the lava which flows beneath. The sections exposed in their walls show the lava field to consist of numerous very thin beds, partly surface flows, but probably in many cases intrusive sheets. This structure is very similar to that of the "pit craters" in Hawaii, the mode of formation of which is still unsettled. Possibly they may have been formed in the same way.

Other interesting points noticed were the formation of moulds by lava flowing round living tree trunks. The trees were, of course, killed, and when they decayed hollows were left corresponding to their former shapes. Occasionally, after the lava had solidified round a tree the remainder had flowed away; when the tree decayed a sort of hollow pillar was thus left, in which smaller plants sometimes grew.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—The Huxley lecture will be delivered on November 23 by Prof. Percy Gardner, professor of classical archæology in the University of Oxford. The subject of the address is "Rationalism and Science in Relation to Social Movements."

BRISTOL.—In connection with the faculty of engineering provided and maintained in the Merchant Venturers' Technical College, a course of five monthly lectures on "Aviation" has been arranged. The selected lecturers are Prof. W. Morgan, Mr. A. R. Low, Mr. E. S. Bruce, Mr. L. Blin Desbleds, and Mr. Joseph Clarkson.

A new wing erected for the chemical and physiological

departments of the University, at a cost of 50,000*l.*, was opened by Lord Winterstoke on November 15.

CAMBRIDGE.—On Saturday last, November 12, a large assembly of physicists from all parts of Great Britain, and many members of the University, came together in the Cavendish Laboratory on the occasion of the presentation to Sir J. J. Thomson of a volume entitled "A History of the Cavendish Laboratory, 1871–1910." The volume had been prepared to commemorate the completion of the twenty-fifth year of Sir Joseph Thomson's tenure of the Cavendish professorship of experimental physics. The presentation was made by Dr. R. T. Glazebrook, director of the National Physical Laboratory, who was for many years associated with the late and present Cavendish professors. The volume begins by recording the fact that perhaps no post in the world has held three men of such supreme and varied genius as James Clerk-Maxwell, Lord Rayleigh, and Joseph John Thomson. It contains a remarkable record of work, and concludes with a list of the memoirs which have been published in connection with the Cavendish Laboratory, which extends over forty-two pages, and a list of some two hundred men of science who have researched in the laboratory. We hope to publish a review of the volume in an early issue.

Mr. A. Hutchinson, of Pembroke College, has been appointed chairman of the examiners for the Natural Sciences Tripos, 1911.

Mr. J. S. Edkins, of Gonville and Caius College, has been approved by the general board of studies for the degree of Doctor in Science.

LIVERPOOL.—On November 14 the honorary degree of LL.D. was conferred by the University upon Sir Archibald Geikie, K.C.B., president of the Royal Society.

OXFORD.—The Herbert Spencer lecture on "Evolution, Darwinian and Spencerian," will be delivered by Prof. R. Meldola, F.R.S., on December 8 at 2.15 p.m.

IT is announced in *Science* that the State legislature of Arkansas has voted 70,000*l.* for the erection of four agricultural schools, and 100,000*l.* additional has been raised by the cities.

WE learn from the *Revue Scientifique* that the buildings of the medical faculty of the University of Toulouse were partially destroyed by fire on October 27. The library of more than 60,000 volumes was burnt entirely, and also the physiological lecture theatre and other rooms.

THE Department of Agriculture and Technical Instruction for Ireland has issued a programme of the Irish Training School of Domestic Economy for the session 1911–2. The school is situated at St. Kevin's Park, Kilmacud, Stillorgan, co. Dublin. The premises stand in grounds of about three acres, and the house provides ample accommodation for the staff and students, in addition to class and recreation rooms. A large fruit and vegetable garden is attached to the house. At the close of each school year, the Department, on consideration of the results of the examination held at the close of the course of household management, and the reports of their inspectors and of the teaching staff, selects for training as teachers of domestic economy a limited number of students who have shown themselves most capable of taking full advantage of the course of training provided. The course of training extends over at least two whole sessions, and involves a complete course of domestic economy suitable for teachers of this subject. It includes the principles of practical elementary science involved in domestic work; cookery; laundry; dressmaking and home sewing; housewifery (including household routine and the keeping of accounts); and practice in the teaching of these subjects. Practical instruction in home hygiene and sick nursing is afforded, and instruction is given in the theory and practice of education.

IN a letter to the *Yorkshire Observer* of November 11 Prof. R. Meldola, F.R.S., urges the need for the provision in this country of a larger number of scholarships for research. "Why, in the name of all that is sacred to the industrial welfare of this country, are not some of the vast sums now devoted to educational purposes available for research scholarships in existing institutions?" asks Prof. Meldola. Later in his letter he says, everything is ripe for the movement. There are competent teaching staffs; there is always a supply of promising students; there are funds from county councils and from public and private endowments; and there is the Treasury behind the Board of Education. There are scholarships given for all kinds of purposes other than for the continuation of the education of the most promising technical students in the institutions in which they received their preliminary training so as to enable them to add one or two years in learning to wield that most powerful of all educational and industrial weapons—the faculty of originality. And to crown all, the manufacturers and employers in this country are now beginning to take a more enlightened view of the situation, and are prepared to employ such men—when they can get them. It seems preposterous that year after year we should see ability, talent, and even genius slipping through our hands for want of means, when educators on one hand and employers on the other are both ready to play their part in promoting the industrial development of the country. We want, he concludes, a system of technical research scholarships which will be looked upon as a distinction to gain, for none but the most competent would be allowed to hold them. We want through such means to strengthen and encourage the work of the teachers by filling their laboratories with research students, and we want to advance British industry by handing over to the manufacturers the picked material from our educational institutions. As a leading article in our contemporary points out, there is no reason why the success which has attended the efforts of Prof. Arthur G. Green and his colleagues at Leeds University in encouraging among the advanced students of applied chemistry research in connection with the art of dyeing should not follow similar efforts in other centres.

IN Dr. Muir's report on education in Cape Colony in 1909, which has come to hand, he shows that in 1891 there were five colleges in the colony where students could pursue courses of study for a university degree, viz. the South African College, Cape Town, the Diocesan College, Rondebosch, the Victoria College, Stellenbosch, St. Andrew's College, Grahamstown, and the Gill College, Somerset East. A large proportion of the teaching power, however, in all these institutions was given to what was, properly speaking, school work, namely, the preparation of large classes for matriculation. Mathematics and chemistry, too, were the only sciences for the teaching of which provision was made. From its inauguration the policy pursued by the Education Department kept three aims in view. The first was the removal of the matriculation classes from the colleges, so that professors might have more time for advanced work, while the pupils of the junior classes might in the public schools be under a discipline more suitable to their years. The second was the institution of new professorships, more especially in the sciences, until then unrepresented; and the third was a reduction in the number of colleges—a number which seemed at the time excessive for the total number of students. Victoria College, Stellenbosch, was the first that agreed to part with its matriculation classes, the junior class in 1896 and the senior in 1899. In the latter year the South African College was induced to follow the example. At present practically all the colleges have ceased to retain matriculation classes. Since 1891 there have been instituted in connection with the colleges professorships of physics, applied mathematics, geology, botany, and zoology. In addition to the then existing courses in arts, law, and survey, there have been opened new courses in arts as well as professional courses in mining, civil and electrical engineering, medicine (preliminary), and forestry. On the literature side there has also been development, professorships in history and lectureships in Hebrew having been established in connection with the larger colleges. The movement towards greater concentration of effort in fewer colleges has been brought to a successful issue in the eastern province. The Gill College, Somerset East, has been closed, St. Andrew's College has restricted itself to school work, and in Grahamstown, by the happy union of all interests, the Rhodes University College has taken their places and become the centre of higher education for the eastern province.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 10.—Sir Archibald Geikie, K.C.B., president, in the chair.—Sir George **Darwin**: (1) The tidal observations of the British Antarctic Expedition, 1907; (2) a mistake in the instructions for a certain apparatus in tidal reductions.—F. **Soddy** and A. J. **Berry**: Conduction of heat through rarefied gases.—II. The thermal conductivities of argon, helium, and hydrogen at very low pressure have been examined in greater detail with new and improved apparatus. The hypothesis provisionally put forward (Roy. Soc. Proc., A, vol. lxxxiii., 1910, p. 254), that the interchange of energy on impact is imperfect in the lighter gases, has been tested and found not to account for the smallness of the ratio (K/Q) of the found to the calculated conductivities. The conductivity of hydrogen using a palladium hot wire is the same as that with a platinum wire. Change of temperature of the hot surface, that of the cold surface remaining constant at room temperature, does not exert so much influence on the value of K as was anticipated. The value of K/Q tended to diminish as the difference of temperature increased, especially at high temperatures. At low temperatures, attained by immersing the apparatus in liquid air and in solid carbon dioxide and ether, the ratio K/Q is *diminished*, whereas on the hypothesis of imperfect interchange of energy an increase was expected. Jacketing the apparatus with vapours up to 264° caused an increase in the value of K/Q. It appears that, most probably, increase in the difference of temperature between the surfaces tends to decrease the value of K/Q, whereas increase in the temperature of both surfaces increases it. Argon under some of the new conditions tried conforms to the theory hardly better than the other gases, and the agreement found previously was probably fortuitous. The general conclusion is that the conductivity at low pressures varies less with the nature of the gas and with the temperature of the experiment than is to be expected from kinetic considerations. The extreme values found for the conductivities of the three gases over a range of about 450° lay between 0·8 and 3·4, whereas the calculated values lie between 0·95 and 16·2 ($\times 10^{-5}$ calorie, per sq. cm. of hot surface, per 1° difference of temperature, per 0·01 mm. pressure of gas).—W. H. **Hatfield**: The chemical physics involved in the precipitation of free carbon from the alloys of the iron-carbon system. The intention of the author is to examine the conditions under which free carbon is produced in iron and steel. Whereas it has been an open question as to whether or not free carbon could be produced direct from the solid solution, the paper is intended to prove the truth of the theory that free carbon can only be produced by the dissociation of the free carbide. It is hoped to demonstrate that this theory holds good through the whole range of the alloys in which free carbon, whether as graphite or annealing carbon, is found. After the presentation of evidence in support of this view of the production of graphite in and near the freezing range, experiments, performed to determine the chemical physics underlying the liberation of annealing carbon in white cast iron, are described. By the electrolytic method of analysis the cementite carbide was obtained from such irons of varying composition, and it is shown how, by varying the percentage of silicon, manganese, or sulphur in the iron, the composition of the cementite is modied and its degree of stability at varying temperatures determined. It is also shown that the size and structure of the precipitated annealing carbon is largely due to the size and structure of the original cementite. Experiments performed to produce annealing carbon in blister steel during the cementation process are then described, after which an explanation of the phenomena of "black" steel is discussed; it is shown that the free carbon found in such steels may present one of two formations, each produced under different conditions. The author further endeavours to demonstrate that whilst the free cementite carbide is dissociated at high temperatures through the whole range of the alloys, the carbide remaining in solid solution does not dissociate until the resolution of the solid solution into the carbide and iron of the pearlite, at the carbon change point.—Dr. F. **Horton**: A spectroscopic investigation of the nature of the carriers of positive electricity from heated aluminium phosphate. The emission of positive ions from substances heated in a vacuum has been investigated by several experimenters, and it has been found that the ratio of the charge to the mass of the ions is the same for all the substances so far experimented on. Assuming that the charge is equal to that carried by the hydrogen ion in electrolysis, the mass of the carriers of positive electricity from heated substances must be about twenty-six times that of the hydrogen atom. The object of this research was to obtain the spectrum of these ions. Aluminium phosphate was chosen for investigation, because of the very large positive ionisation produced on heating this substance. A calculation showed that, with the apparatus used, it might be expected to collect a sufficient quantity of the carriers to obtain their spectrum in a small vacuum tube. The vessel used to collect the carriers was cooled in liquid air during the passage of the thermionic current from a strip of platinum covered with aluminium phosphate to a surrounding platinum cylinder. The material collected was then allowed to vaporise, and its spectrum was obtained by rendering it luminous with an electrodeless ring discharge. The spectrum of carbon monoxide was always obtained, although precautions had been taken to exclude this gas, or materials which might give rise to it, from the apparatus. It is concluded, therefore, that the positive ions consist of carbon monoxide, the molecular weight of which agrees fairly well with that required by the results of the e/m determinations. It is considered improbable that this gas is evolved on heating every substance which has been experimented on in the determinations of the specific charge, but from the nature of the apparatus used it must always have been present during these determinations. In the paper reasons are given for believing that molecules of carbon monoxide readily act as carriers of positive electricity, and this gas probably diffuses into the hot metal or other substance and is evolved in an ionised state.—N. **Bohr**: The determination of the tension of a recently formed water-surface. Arguments in further support of the author's previous conclusion, that the surface tension does not change sensibly with the time that has elapsed since the surface was formed.—Lord **Rayleigh**: Aërial plane waves of finite amplitude.—J. J. **Manley**: Observations on the anomalous behaviour of delicate balances, and an account of devices for increasing accuracy in weighings.—Prof. F. W. **Dyson**: The improbability of a random distribution of the stars in space.—G. I. **Taylor**: The conditions necessary for discontinuous motion in gases.—The Hon. R. J. **Strutt**: (1) The radium content of basalt; (2) measurements of the rate at which helium is produced in thorianite and pitchblende, with a minimum estimate of their antiquity.

Royal Microscopical Society, October 19.—Mr. E. J. Spitta, vice-president, in the chair.—J. J. **Simpson**: Hicksonella, a new gorgonellid genus. The genus is established to include three species, all collected off South Africa. One species was described by Prof. Hickson in 1904 under the name of *Juncella spiralis*, but the author believes that a reference to the genus Juncella is impossible. The clearing up of the position of this puzzling specimen was facilitated by recent work of the author in his revision of the family of the Juncellids. In addition to *Hicksonella spiralis*, g.n., he describes *H. flagellata*, sp.n., and *H. capensis*, sp.n.—E. **Heron-Allen** and A. **Earland**: Some varietal forms of *Massilina secans*. After referring to several varietal forms that had been previously described, the authors related the finding of numerous specimens of three of these varieties in narrow observation tanks where some gatherings of Foraminifera, made off Selsey Bill, had been placed, and where they multiplied. The conclusion arrived at was that these variations were caused by the want of sufficient shell-making material, the carbonate of lime in the tanks having been used up, the sea water never having been renewed.—E. M. **Nelson**: A micrometric difficulty. The author referred to the difficulty of counting correctly the number of ruled lines, or diatomic striæ, in a given space. The trouble does not arise when the interspaces are relatively wide compared with the breadth of the lines, but it does so when the breadth of the interspaces approaches that of the lines. It is the black and white dot image that is

responsible for the trouble. When the focus is at a white-dot image the white lines must be counted, and *vice versâ* when the focus gives a black-dot image.—E. M. **Nelson**: The resolution of new detail in a *Coscinodiscus asteromphalus*. This paper has refeience to the resolution of further detail obtained by a new one-eighth objective by Zeiss, described in a previous communication. The new detail discovered is a fine sieve covering the so-called eye-spot in *C. asteromphalus*. As the size of the eye-spot is only 1/14,000th of an inch, it may be left to the imagination to estimate the size of the minute perforations forming the sieve.

Physical Society, October 28.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Prof. Ernest **Wilson** and W. H. **Wilson**: A new method for producing high tension discharges. According to this method energy is taken from an alternating or continuous current source and stored in a magnetic field by an inductance; it is then permitted to surge into a condenser which forms with the inductance a *low* frequency oscillating circuit. When the energy is stored in the condenser the latter is mechanically bridged across the primary winding of a spark-coil, with which it forms a *high* frequency oscillatory circuit. The energy is then transmitted by the secondary winding of the spark-coil to the work circuit in the well-known manner. Briefly the following are some of the advantages gained:—(1) For X-ray work the inverse electromotive force at "make" is eliminated, thereby leading to increased life of the tube and to a more sharply defined radiograph. (2) Only a small magnetising current is required as the inductance has a nearly closed magnetic circuit. This gives rise to a very small C^2R loss and consequently higher efficiency. (3) On account of the long periodic time of the system between the periods of "break" and "short-circuit," the voltage across the contact of the interrupter at "break" does not rise to a high value, or rises so slowly that the contacts are well separated before it is developed. Hence immunity from sparking. (4) The method lends itself to few secondary turns and this keeps down the time constant. It also makes the coil lighter, cheaper, and more compact. (5) The method lends itself to low secondary resistance—a point of great importance in connection with radio-telegraphy. (6) The iron of the spark-coil can be kept small in amount, and special attention can be paid to its lamination and insulation, as it may have to be operated at frequencies of three or four thousand per second. (7) The elimination of sparking increases efficiency, and on board ship where coal gas is not conveniently obtainable this is an advantage. (8) The apparatus can be worked from direct-current or alternating-current systems at usual voltages, or from a portable battery of a few storage-cells. (9) The oscillatory current at "break" does not pass through the battery, and hence does not assist in its discharge. (10) The iron in the magnetic circuit of the external inductance has only to operate at low frequency, and hence it has not to be finely laminated. (11) When used on alternating-current systems, rectification, if desired, is easily effected by employing two short-circuiting brushes, one for each half-period, and allowing the second brush to short-circuit at the moment when the condenser is fully charged after allowing a second complete surge of the energy between the condenser and the inductance of the spark-coil. (12) The apparatus is light, efficient, and cheap, and is suitable for radio-telegraphy, X-ray, medical, and other work in which high-tension electricity is employed.—F. **Rogers**: The behaviour of steel under combined static stress and shock. Attention is directed to the importance of the time rate of increase of stress, ds/dt, in the behaviour of materials under stress. The exact determination of this rate must usually present much difficulty, but the indirect experimental method adopted consisted in submitting specimens of steel to shock whilst under static loading. The conclusion that steel is substantially less resistant to shock whilst it is under static stress appears to be definitely established. In some cases the effect of a large static stress was to diminish the resistance to shock by as much as 30 per cent. The correction for the work done upon the sample in applying the static load is relatively small. Thus the energy absorbed in breaking a sample of steel is greater when entirely applied as shock than when applied partly as shock and partly statically. This difference is considered to be due chiefly to the difference in the rate of increase of stress at the higher stresses in the two cases. The actual values of the highest stresses are not necessarily identical, but probably the higher the rate of increase of stress the higher is the greatest stress reached before rupture occurs, whilst, simultaneously, deformation is diminished, and the intimate nature of the breakdown suffers a corresponding variation. At the higher static loads employed some portions of the test-pieces were stressed beyond their elastic limits, and this may also help to account for a part of the diminution in resistance to shock.

Linnean Society, November 3.—Dr. D. H. Scott, F.R.S., president, in the chair.—Prof. W. A. **Hordman**: A comparison of the summer plankton on the west coast of Scotland with that in the Irish Sea. This paper is the result of a series of vertical plankton hauls taken with the "Nansen" closing tow-net (made of No. 20 silk) from the S.Y. *Ladybird* in July of the last four years, from various deep hauls (eighteen of them being from more than 100 fathoms) at various localities off the west coast of Scotland. A comparison of the collection shows (1) that there is a constancy year after year in the nature of the plankton at certain localities; and (2) that some of the localities, not very far apart, differ considerably from one another in the nature of their plankton at the same time of year (July). Some of these deep hauls consist markedly of zoo-plankton and others of phyto-plankton, and the latter show a close resemblance to the phyto-plankton hauls typical of the vernal maximum of diatoms in the Irish Sea. The complete disappearance of the phyto-plankton, which is such a marked feature in the summer (July and August) gatherings from the Irish Sea, does not seem to take place in some localities off the west coast of Scotland, and these phyto-plankton hauls are obtained, not in the deep fiord-like lochs, but in the open sea, *e.g.* off Ardnamurchan and off the islands of Rum and Canna in the Sea of the Hebrides.—J. C. F. **Fryer**: The structure and formation of Aldabra and neighbouring islands, with notes on their flora and fauna. Aldabra, situate 250 miles north-west of Cape Amber, is a large atoll with an almost complete land-rim, a large shallow lagoon, and a narrow fringing reef. The land-rim is composed of coral-limestone, which gives definite evidence that Aldabra was formed by elevation and once stood at more than 40 feet above sea-level, though rain-water denudation has reduced this to its present level of 15 feet. A deposit of guano, by combination with the limestone, has produced phosphatic rocks, interesting in that they prove that the lagoon was once non-existant, and has since been formed by erosion and denudation. The atoll is still being washed away, but the loss is in part compensated by the piling up of sand by wind and wave. The fauna and flora, though peculiar, have been largely derived from Madagascar, the flora being interesting in showing four distinct types of jungle. Assumption, Cosmoledo, Astove, are also islands and atolls of elevated coral-rock, and form an interesting series showing the loss of rock-land by erosion and its replacement by sand and clays. Giant land-tortoises still exist on Aldabra, and fossil remains were found on the three other islands visited; in this connection it is noteworthy that none of these islands has ever been connected with continental land.—H. B. **Bigelow**: The Siphonophora of the *Research* Biscayan plankton. The memoir forms the thirteenth report on Biscayan plankton collected on board H.M.S. *Research* in 1900. The collection consisted exclusively of Calycophoridæ, with the exception of a single fragment from another group. In his report of the Siphonophora of the *National*, Prof. Chun noted a similar absence of Physophoridæ during the North Atlantic summer, and suggested that these latter forms must be at considerable depths at that season, yet the numerous hauls of the *Research* with closing nets down to really great depths failed altogether to find them. On the other hand, it is only during summer that these Physophoridæ are found on the eastern coasts of North America, at a time when the cold current alongshore is at its warmest; and further, they were not uncommon in July and August during cruises of the *Research* in the Færöe Channel, in the cooler water of

more northern origin. All these facts seem to point to rather narrow limits, outside of which the Physophoridæ perhaps die down to a large extent seasonally, except for a few specimens which will reproduce when the temperature optimum is again reached. The second point of interest to which the author directs attention is that all the ten species captured—except one new genus and species—were also taken in the eastern Pacific expedition of the *Albatross* under the late Prof. Alexander Agassiz. The collection included one new species of Diphyes and one new genus, Nectopyramis, apparently a monophyid. On the question of vertical distribution, which was a main object of the cruise, the author has arrived at some conclusions of interest. The Calycophoridæ were comparatively rare at the surface, but most plentiful somewhere below 25 and above 100 fathoms. The only species taken sufficiently often to allow of discussion was *Diphyes appendiculata*. The diphyid or polygastric generation was uncommon at the surface, seemed to reach its plurimum about 75–100 fathoms, and below that was very seldom met with. The eudoxid or sexual generation, on the other hand, presented a plurimum at the surface, was taken less often down to 100 fathoms, and only once below that depth, namely, between 400 and 500 fathoms. Another form captured, *Chuniphyes multidentata*, has so far been recorded only from considerable depths; the captures by the *Research* fix it as low as between 2000–1000 fathoms, that is, between nearly $3\frac{1}{2}$ miles and 2 miles deep. The highest capture was in an open net hauled for an hour at 250 fathoms, and thence to the surface; but as it was taken in none of the ninety-five hauls above 250 fathoms, this is probably about its upper limit.

Mathematical Society, November 11.—Sir W. D. Niven, president, and subsequently Dr. H. F. Baker, newly elected president, in the chair.—Sir W. D. **Niven**: The relations of mathematics to experimental science (presidential address).—G. T. **Bennett**: The double-six of lines. Dr. W. H. **Young** and Mrs. **Young**: The existence of a differential coefficient.—Dr. W. H. **Young**: (1) Note on the property of being a differential coefficient; (2) conditions that a trigonometrical series may have the Fourier form.—F. **Tavani**: A class of integral functions which includes Riemann's Zeta-function.—T. W. **Chaundy**: The geometrical representation of non-real points in space of two and three dimensions.—J. E. **Littlewood**: The extension of Tauber's theorem.—F. B. **Pidduck**: The stability of rotating shafts.—J. E. **Campbell**: A class of orthogonal surfaces.—S. **Chapman**: Non-integral orders of summability of series and integrals.—Dr. A. R. **Forsyth**: Lineo-linear transformations, especially in two variables.—Dr. W. F. **Sheppard**: Notes on terminating hypergeometric series.—H. **Bateman**: The transformation of a particular type of electromagnetic field and its physical interpretation.—Dr. P. **Mahlo**: Über die Dimensionentypen des Herrn Fréchet im Gebiete der linearen Mengen.

MANCHESTER.

Literary and Philosophical Society, October 18.—Mr. F. Jones, president, in the chair.—Prof. G. Elliot **Smith**: The convolutions of the brain. The cortex is mapped out into a great number of territories, differing in structure and function, and varying in size in different mammals, not only because the sense-organs themselves vary in size and acuteness in different creatures, but also because in different orders and families a sense organ of a given size will have a varying cortical representation. Thus, if one were to take a dog and a baboon with eyes of the same size, the monkey will be found to possess a much larger cortical visual area than the dog. It is these differences which determine the varied plans of cortical folding and the resulting varieties in the patterns of the convolutions in different mammals. Folding occurs most often along the boundary line between two areas of different structure and function. The difference in the rate of expansion of two such areas is no doubt the reason for this type of fissure-formation—limiting sulci. In the second place a rapidly growing cortical territory, meeting with obstruction to its expansion on all sides, may become buckled in, and so a furrow develops along its axis (*i.e.*, within its area), instead of at its edges. This second class of furrow is much less frequent than the first class, and may be distinguished as the group of axial sulci. There is a third variety, which may be called the operculated sulcus, in which one lip projects over a submerged area. Sulci of this type are produced by the submerging of a specialised fringing territory surrounding a main sensory area. In the fourth place various mechanical factors come into operation to modify the form of furrows formed in one of these three ways, or even to produce new sulci. By the application of these principles it is possible to interpret the meaning and the mode of formation of most of the furrows which subdivide the higher types of cortex into numerous convolutions.

November 1.—Mr. Francis Jones, president, in the chair.—Dr. A. N. **Meldrum**: The development of the atomic theory. (ii) The various accounts of the origin of Dalton's theory. (iii) Newton's theory and its influence in the eighteenth century. There are numerous accounts of the genesis of Dalton's theory, one of which comes from W. C. Henry, another from Thomas Thomson, a third from J. A. Ransome, and two come direct from Dalton. All the narratives come from Dalton originally, for Henry, Thomson, and Ransome based theirs on conversations they had with him. The discrepancies between these various accounts can be explained only on the supposition that Dalton was deficient in historical instinct, and never appreciated the difference between describing the genesis of his theory and expounding the theory itself. The main conclusions of the second paper are (1) that Newton's contribution to the development of the atomic theory was made under the influence of Descartes; (2) that Newton exerted an influence in the eighteenth century on Bryan Higgins, and through him on William Higgins. The atomic theory advanced by Bryan Higgins (1776) and amplified by William Higgins (1789) can be understood only when regarded as springing from Newton's theory under the conditions of the time. Those conditions were:—(*a*) the knowledge due to Priestley of different kinds of gases, and (*b*) the new light which Lavoisier threw on chemical composition, consequent on Priestley's discovery of oxygen.

PARIS.

Academy of Sciences, November 7.—M. Émile Picard in the chair.—M. **Bassot**: Halley's comet. Observations of this comet were made at the Observatory of Nice on November 2 and 3. It is visible in the morning a little before sunrise. The sky was covered on the nights of November 4 and 5, but in spite of the absence of a third observation there is no doubt of the identity of the comet.—A. **Müntz**: The struggle for water between the soil and the seed. For each specific kind of soil there is a definite percentage of moisture, below which the seed, instead of gaining moisture, actually loses it. For the seed to absorb sufficient water to be able to germinate, a higher percentage of moisture, fixed for each class of soil, is necessary. Thus in a sandy soil 0·5 per cent. of water is sufficient for germination; with loams the required percentage of water is from $2\frac{1}{2}$ to 7·7 per cent., according as the proportion of clay increases; with a garden soil containing a large proportion of humus, nearly 10 per cent. of water must be present before germination can take place.—Charles **Nordmann**: A means of determining by colour photometry the parallaxes of a certain class of stars. First application to two stars. The method applied to Algol gives a distance of 59 years of light, or a parallax of 0·055″, a figure in good agreement with the 0·051″ given for this star by M. Bijourdan in his recent catalogue of stellar parallaxes. The same method applied to δ Libra gives a distance of 355 years of light and a parallax of 0·009″.—A. **Demoulin**: Certain couples of triple-orthogonal systems.—W. **Stekloff**: The development of an arbitrary function in series of fundamental functions.—L. **Favé** and L. **Driencourt**: Observations of the tides made at sea in the Channel and the North Sea. A self-recording instrument has been devised by the authors which, when placed on the sea floor, measures pressure variations directly, from which the changes of level due to the tides can be deduced. An automatic differential arrangement renders the sensibility very nearly independent of the depth. A diagram is given of observations taken at a point situated 52° 29′ N., 0° 47′ E., and the bearing of these data upon Whewell's work on the tides of the North Sea is discussed.—A. **Petot**: Unsymmetrical motors.—Eugène **Bloch**: The action of a magnetic field on the electric

discharge. The author has repeated and confirmed some experiments recently made by M. Gouy, and finds that there is a particular strength of the magnetic field which facilitates the maximum discharge. It is shown that this curious phenomenon is in general agreement with the modern theory of disruptive discharge.—J. **de Kowalski**: Progressive phosphorescence at low temperatures.—A. **Guntz** and M. **Galliot**: The preparation of crystallised strontium. A mixture of strontia and aluminium powder is placed in the lower half of a steel tube closed at one end. This is enclosed in a porcelain tube, a high vacuum being maintained in the latter. The temperature of the mixture is gradually raised to 1000° C.; after cooling, the inside of the cool portion of the tube is covered with a deposit of crystalline strontium. The yield is good, nearly 75 per cent. of the theoretical quantity, and the metal contains only 0·5 per cent. of impurities.—E. **Berger**: Tetranitromethane. This substance is obtained by the action of pure nitric acid upon acetic anhydride in acetic acid solution. The exact conditions necessary for a good yield (50 per cent. of the theory) are given in detail. The physical constants and the heat of combustion were determined.—E. **Kayser**: The influence of nitrates on alcoholic ferments. Alcoholic fermentation is more complete in presence of manganese nitrate, and for each strain of yeast there is an optimum amount of salt, the addition of which produces a maximum of diastatic activity.—G. **Malfitano** and Mlle. A. N. **Moschkoff**: The purification of starch. A 1 per cent. colloidal solution of starch is prepared, the turbid liquid frozen and allowed to melt. The clear liquid thus obtained holds in solution the greater part of the mineral impurities and very little starch; the bulk of the latter deposits in flocculent form, and can be separated by filtration or by centrifugation. After four or five repetitions of this treatment a starch is obtained which gives less than 0·02 per cent. of ash. The properties of starch thus purified are compared with those of ordinary starch. —M. **Marage**: Subjective noises in the ear. A classification of the various kinds of subjective noises in the ear in accordance with their pathological causes.—Henri **Labbé**: The distribution of nitrogen in the intestinal excreta. The dried excreta were extracted successively with various solvents, and the nitrogen determined in each extract.—S. **Lalou**: The variations in the quantity and composition of the pancreatic juice during secretions brought about by secretin. Repeated injections of secretin produce a regular secretion of pancreatic juice during a long period. The juice thus obtained is not of strictly constant composition; its alkalinity and diastatic activity diminish, this diminution being especially marked as regards the lipase.—P. **Chaussé**: Latent mesenteric tuberculosis produced experimentally in the dog. The injection of tuberculous products in the normal dog produced no visible lesions after six months. Latent mesenteric tuberculosis was, however, easily shown to exist in the majority of the dogs under experiment.—M. **Fabre-Domergue**: The food of the oyster and the mechanism of its contamination in impure water.—R. **Robinson**: Contribution to the study of the venous circulation in the lower limbs.—Paul **Marchal**: Contribution to the biological study of Chermes.—A. **Quidor**: The evolution and affinities of the Philichthydæ.—O. **Mengel**: Geology of the primary islet of La Guardia between Sègre and Noguera Pallaresa.—H. **Mansuy**: The stratigraphic succession in the neighbourhood of Luang-Prabang.—Maurice **Leriche**: The first fossil fishes met with in the Belgian Congo in the Lualaba strata.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 17.

ROYAL SOCIETY, at 4.30.—On the Effect of Gravity upon the Movements and Aggregation of *Euglena viridis*, Ehrb., and other Micro-organisms: Harold Wager, F.R.S.—The Proteolytic Enzyme of Drosera: Miss Jean White.—The Influence of Bacterial Endotoxins on Phagocytosis (including a new method for the Differentiation of Bacteria). (Second Report): L. S. Dudgeon, P. N. Panton, and H. A. F. Wilson.—On the State of Aggregation of Matter. Part I. On the Action of Salts in Heterogeneous Systems, and on the Nature of the Globulins. Part II. On the Action of Formaldehyde on Witte's Peptone. Part III. On the Solubility of Phenol and certain Crystalline Substances in Salt Solutions: Dr. S. B. Schryver.—A Method for Isolating and Growing the Leprosy Bacillus of Man: F. W. Twort.—The Oxidation of Phenol by certain Bacteria in Pure Culture: G. J. Fowler, E. Ardern, and W. T. Lockett.

LINNEAN SOCIETY, at 8.—(1) Theoretical Origin of *Plantago maritima* and *P. alpina*, from *P. coronopus*; (2) Supplementary Observations on the Theory of Monocotyledons being derived from Aquatic Dicotyledons: Rev. George Henslow.

ROYAL GEOGRAPHICAL SOCIETY, at 5.—Research Meeting. Origin of the Present Geography of Northern Nigeria: Dr. J. D. Falconer.

FRIDAY, NOVEMBER 18.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—The Development of Road Locomotion in Recent Years: L. A. Legros.

MONDAY, NOVEMBER 21.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Duke of Abruzzi's Karakoram Expedition: Dr. Filippo de Filippi.

ROYAL SOCIETY OF ARTS, at 8.—Industrial Pyrometry: C. R. Darling.

TUESDAY, NOVEMBER 22.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.30.—The Arrival of Man in Britain in the Pleistocene Age: Prof. W. Boyd Dawkins, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Portland Cement, and the Question of its Aeration: H. K. G. Bamber.

WEDNESDAY, NOVEMBER 23.

ROYAL SOCIETY OF ARTS, at 8.—Methods of Detecting Fire-damp in Mines: Sir Henry H. Cunynghame, K.C.B.

GEOLOGICAL SOCIETY, at 8.—The Effects of Secular Oscillations in Egypt during the Cretaceous and Eocene Periods: Dr. W. F. Hume.—The Origin of the British Trias: A. R. Horwood.

THURSDAY, NOVEMBER 24.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: Colour-blindness and the Trichromatic Theory. Part II. Incomplete Red or Green Blindness: Sir W. de W. Abney, K.C.B., F.R.S.—On the Sequence of Chemical Forms in Stellar Spectra: Sir N. Lockyer, K.C.B., F.R.S.—The Influence of Viscosity on the Stability of the Flow of Fluids: A. Mallock, F.R.S.—An Electrostatic Voltmeter for Photographic Recording of the Atmospheric Potential: G. W. Walker.—Optical Dispersion, an Analysis of its Actual Dependence upon Physical Conditions: Dr. T. H. Havelock.—The Spectrum of Halley's Comet: C. P. Butler.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Street Lighting by Modern Electric Lamps: H. T. Harrison.

FRIDAY, NOVEMBER 25.

PHYSICAL SOCIETY, at 5.—The Electric Stress at which Ionisation begins in Air: Dr. A. Russell.—On the Measurement of a Flow of Water in a Closed Circuit by a method involving little or no Statical Friction: Dr. A. Griffiths.—Exhibition of a Surface Brightness Photometer: J. S. HIGHER ASPECTS OF ELECTRICITY.

A Treatise on Electrical Theory and the Problem of the Universe, considered from the Physical Point of View, with Mathematical Appendices. By G. W. de Tunzelmann. Pp. xxxii+654. (London: Charles Griffin and Co., Ltd., 1910.) Price 15*s*. net.

THE partial success which has attended the recent attempts of Einstein and Minkowski to found an electromagnetic system of mechanics has tended to strengthen the popular idea that the solution of outstanding problems and mysteries must be sought in the domain of electrical rather than other physical phenomena. From being a disturbing element characterised by unaccountable vagaries, the "electric fire" has come to be an all-pervading element, closely approaching the alchemist's idea of a primal substance. Mr. de Tunzelmann's work is an ambitious attempt to apply the Faraday-Maxwell theory of electricity, as modified by Larmor in the atomistic direction, to what he calls "the problem of the universe." Incidentally, the book gives a great deal of information with regard to recent work and speculation, and although the titular object of the work has not been attained (it could hardly be otherwise in our present state of knowledge), it will be valued on account of the information given on such varied subjects as electrolysis, radiation, radio-activity, the age of the earth, the solar corona, and the place of mind in the universe.

As might have been expected in a book of this kind, the interstellar ether plays a fundamental part in most of the ultimate speculations. That being so, it is to be regretted that no serious attempt was made to present the modern aspects of the various ether theories. Possibly the author may have considered the matter as too controversial. The electromagnetic principle of relativity (as distinguished from the mechanical or Newtonian one) is of such outstanding importance that it is quite impossible to state modern electrical problems without at least acknowledging its existence. Yet, neither in chapters v. nor xxii., where some statement of the principle is urgently called for, nor indeed in any other part of the work, is it even mentioned. And, although Le Sage's hypothesis and its later variants are dealt with to a remarkably full extent, there is no reference to H. Witte and his proof that the only chance for a mechanical explanation of electrical phenomena lies in the assumption of an ether composed of discrete particles.

Of minor blemishes we have "cathion" instead of "cation" (p. 19) evidently due to mistaken etymology, a micromillimetre described as "a thousandth of a millimetre" (p. 321), "coronarium" instead of "coronium" (p. 371), and plain "Norman Lockyer" (p. 644) beside the full titles of other savants. In dealing with magnetism, Langevin's important and successful theory, based upon the Zeeman effect and Curie's law, is not mentioned. In dealing with light, the author suggests calling the velocity of light in space the "radiation constant" (a term already otherwise appropriated), and (p. 271) makes out that an absorbing body absorbs less (instead of more) energy in unit time on being moved in the direction from which the light is coming.

The chapter on "The Place of Mind in the Universe," is a fascinating one, though its connection with the main work is not very obvious. The author aims at an all-embracing system or hierarchy of ultimate realities, beginning at the absolute, or eternal self-consciousness, and passing through mind, energy, and ether down to matter. The chapter is well written, and most suggestive. It is, of course, open to criticism on many points, but as few physicists have the courage to penetrate far into that borderland on the confines of which they, more than others, are wont to dwell, a spirited attempt like the present deserves every encouragement. At a time when the ether is being tried for its very existence, it is unwise to describe such a philosophic scheme as based upon a substance the properties of which, as the writer somewhat hastily asserts, "are derived from empirical observation." And when that system is further "strengthened" by a reference to the discarded "N-rays," and a single experiment in thought transference unaccompanied by the elementary safeguards devised by the Psychical Research Society, the system put forward is placed at a disadvantage from the first. Nor is that disadvantage removed by too great an insistence on the principle of the conservation of energy, and its use to assign a time-limit to the existence of the visible universe. Such a time-limit is really a negation of science and philosophy, as it implies that *deus ex machinâ* from which all scientific achievement has had to liberate itself or perish.

There are eighteen appendices on miscellaneous electromagnetic and philosophical subjects. Many of these, especially that on astronomical anomalies, are very useful and valuable.

TECHNICAL DICTIONARIES.

The Deinhardt-Schlomann Series of Technical Dictionaries in Six Languages. By Alfred Schlomann. Vol. v., Railway Construction and Operation. Pp. xiii+870. Price 12*s*. net. Vol. vi., Railway Rolling Stock. Compiled by Dipl.-Ing. August Boshart. Pp. xiii+796. Price *10s. 6d. net.* (London: Constable and Co., Ltd.; Munich and Berlin: R. Oldenbourg, 1909.)

THESE two volumes form part of a series of technical dictionaries in six languages—English, Spanish, German, Russian, French, and Italian—of which seven volumes have now appeared. They are edited and compiled by Messrs. Deinhardt and Schlomann, assisted by experts from all the leading countries in each branch of the subject. The essential features of the scheme are that the six languages are all on one page, and, wherever it is possible, sketches are given so as to elucidate the text and facilitate the use of the dictionary. At the end of each volume complete alphabetical indexes are given,

five of the languages under one alphabet, and the Russian under another. The general arrangement, and the ground covered by each volume, leave nothing to be desired, and this dictionary will prove invaluable to all those who are engaged in technical work. Repeated tests of both volumes show that practically nothing has been omitted, and the long lists of contributors and revisers for the two volumes, embracing men eminent in the railway world in Europe and America, are a sufficient guarantee of the accuracy of the work. The great difficulty which often arises of finding a definition in one language which should have its exact equivalent in another has been very satisfactorily overcome, and the sketches render misunderstandings almost impossible.

In the volume dealing with railway construction and operation, only those terms are included which are of general importance in such work; such details as earthworks, bridge-construction, &c., could only be exhaustively treated in volumes specially reserved for them. Nevertheless, the railway expert will find that such subjects have been quite adequately treated so far as he is concerned in this volume. In preparing this volume, the subject has been divided into sections to facilitate reference; these sections include track, permanent-way, connections between tracks, stations, signalling, and safety appliances, railway service, &c., and one special section has been given to electric railway installations. Each section is again divided into a large number of subsections, and, as these are given fully in the table of contents, it will be realised how much care has been taken to facilitate reference. It is essential to those who are engaged in the work of translating or making extracts from foreign technical books and journals that any technical dictionary should be so arranged that no time should be lost in ascertaining the ordinary English equivalents to any unknown foreign words or expressions; the alphabetical index at the end of each volume ensures this, and the division of the whole subject into sections and subsections still further makes for simplicity and saving of time.

The sixth volume is given up entirely to the important subject of railway rolling stock. Here, again, the subject is divided up into a series of sections, such as common equipment for locomotives and carriages, including such details as wheels, axles, drawbar and buffer gear, brakes, &c.; locomotives and motor coaches; carriages; systems of lighting trains; rolling stock for electric railways; and, lastly, railway workshops. This latter section is not, of course, intended to cover the subject of machine tools generally, but only in so far as special methods and working are employed in railway workshops.

With the help of these two volumes, the railway engineer, and all those who are concerned with the various industries which are devoted to the manufacture of the machinery and plant required for the working and upkeep of the railways of the world, will find that the task of keeping abreast of what is being done in other countries will be greatly facilitated. It is essential that every manufacturing firm should endeavour to learn from the technical Press what is being done in other lands, and a thoroughly trustworthy technical dictionary, such as this series now in course of publication, is indispensable for this purpose. These volumes should be found in the head office of every firm which aspires to keep itself up to date in business methods.

T. H. B.

PHYSICAL CHEMISTRY IN ITS GEOLOGICAL APPLICATIONS.

Principles of Chemical Geology: a Review of the Application of the Equilibrium Theory to Geological Problems. By Dr. J. V. Elsden. Pp. viii+222. (London: Whittaker and Co., 1910.) Price 5*s*. net.

ALTHOUGH it is generally recognised that the new physical chemistry has far-reaching applications in geology, no less than in other branches of science, little has yet been done to bring this home directly, either to the working geologist or to the student. In Van 't Hoff's lectures on "Physical Chemistry in the Service of the Sciences," the only geological application discussed is that relating to the crystallisation of salts from sea water. The results of the chemist's beautiful investigation of this one problem are the first-fruits of work on these lines, and they serve to show how wide a field still remains to be harvested. Vogt and others have essayed to apply the laws of solutions to igneous rock-magmas, but in this much more difficult problem no more than a beginning can yet be recorded. Meanwhile, we suffer from that want of touch between workers in different branches of science which is one of the less happy consequences of specialisation. The chemist has, in most cases, little acquaintance with geological questions, while the geologist, of the older generation at least, has not usually a working knowledge of physical chemistry, or at best is unfamiliar with the specific results which have been obtained.

This gap Dr. Elsden has now endeavoured to fill. The book before us is a compendium of physico-chemical principles as applied to the more important questions of chemical geology and petrology. In accordance with this plan, the arrangement adopted is primarily a chemical one, thus differing from the older method of Bischof and others. Successive chapters deal with the crystalline and amorphous states, viscosity, diffusion, solution, surface-tension, vapour-pressure, polymorphism, and mix-crystals. Throughout the author insists that the key to the many problems here touched "lies in the determination of the conditions of equilibrium," and indeed this last word occurs in the heading of almost every chapter. Unfortunately, as is duly recognised, many geological phenomena (such, *e.g.* as the glass in volcanic rocks) prove that the adjustment of equilibrium may be indefinitely delayed.

A surprising amount of matter is brought together in the compass of these two hundred pages, and the numerous references given in footnotes will be very useful to the student. Sometimes, perhaps, this fulness is gained rather at the expense of clearness of treatment; or it may be merely a wholesome caution which makes the author content to cite conflicting opinions and leave the question at issue open. In

general, we are given an admirable, if condensed, summary of the subjects dealt with, though in places a critic may pick out a carelessly written sentence, *e.g.* the dictum (p. 2) that "no substance can at once possess both vectorial and scalar properties." Any work treating of a new and rapidly developing subject must inevitably contain statements which have become obsolete even before their publication, and in a second edition Dr. Elsden will doubtless revise such passages as those relating to quartz and tridymite (p. 104), amphibole and pyroxene (pp. 111 *et seq.*), and lime-olivine (p. 203). Meanwhile, the book, in addition to its intrinsic value, will attain the author's expressed desire to stimulate interest in this important branch of geology. A. H.

THE MAKING OF GARDENS.

Hardy Plants for Cottage Gardens. By Helen R. Albee. Pp. vi+309. (New York: Henry Holt and Company.) Price 1.60 dollars net.

THIS volume forms part of the American Nature Series: Group iv., Working with Nature. From the title one would expect to find the work severely technical and somewhat dull—"dull and useful as work clothes and garden boots," as the author herself describes a certain chapter. But the title, though appropriate for a section of the work, is to some extent inadequate, as the book proves to be an essay on garden-making, written in a light and racy style, reminiscent of Charles Dudley Warner's delightful "My Summer in a Garden."

The greater part of the volume is devoted to a detailed account of the evolution of the author's garden, through the various stages "In the beginning," "An incipient garden," "The garden grows," "My ambition grows," and gliding on by easy transition to such apparently inconsequent subjects as "the vices of plants" and "some gardeners I have known." But though the author in her narrative of the six years' labour involved in the formation of her garden ranges over a wide field of horticultural economy, the sequence is so easy and natural that the reader's interest is not allowed to flag, and it is with regret that one reaches the classified lists which occupy the last 122 pages of the book.

These lists are conventional, and call for little comment. The method of classification adopted, though at first sight somewhat complex, will probably facilitate reference. The lists comprise a selection of shrubs and perennials, with descriptions and brief cultural directions, and are arranged primarily under colour headings, and, secondarily, according to the months in which the plants flower. A selection of annuals arranged according to the same system follows. It may be pointed out that this might have been incorporated with the shrubs and perennials, thereby avoiding a somewhat bewildering multiplicity of headings. The work is profusely illustrated with views of the author's garden at various stages, and a copious index is provided.

The author has not laid down hard and fast rules for the formation of a flower garden. Nor does she desire that others should follow slavishly the lines on which she has worked. "It is not well to imitate another's work, but to follow where your own conditions lead." Her experiences are related with a view to stimulating others who may have the opportunity and the desire to create a garden after their own heart, but who may lack the courage to break away from the conventional or who are diffident as to their ability to shape a new course for themselves. By such the book will be found rich in suggestion. Above all is it a plea for the free play of imagination in the garden.

"No one should have a garden which grows nothing but flowers, and yields no other recompense to the gardener except successful plants. Over, beyond, and above must hover the spirit of poetry, of wonder, of mystery; otherwise there comes a day of disillusion when you awaken to the weariness, anxiety, and watchfulness, and begin to measure the reward. You need a larger insight, something that connects your efforts with the universal in nature, the ideal, the soul of things. Into this you may lift the garden, and at once drop the tired body and soiled hands, and the whole material aspect of labour."

PHARMACEUTICAL PRACTICE.

The Extra Pharmacopoeia of Martindale and Westcott. Revised by Dr. W. Harrison Martindale and W. Wynn Westcott. Fourteenth edition. Pp. xxvii+1054. Price 12*s.* net. With supplement, *Organic Analysis Chart.* By W. H. Martindale. Pp. 80. (London: H. K. Lewis, 1910.) Price 3*s.* 6*d.* net.

THIS handbook, which is so familiar to medical and pharmaceutical practitioners, appears in its fourteenth edition in a slightly altered form, the size of the pages having been enlarged so as to allow of the inclusion of new matter without increasing the thickness of the book. It will, however, still fit comfortably in the coat pocket, which is not an altogether unimportant advantage.

The two years that have elapsed since the appearance of the thirteenth edition have yielded an unusual amount of valuable therapeutic literature, a judicious condensation of which forms, for the most part, the new matter of the fourteenth edition. There are new chapters upon lactic acid bacilli therapy, organic arsenic compounds, the electrical introduction into the tissues of medicaments in the ionised condition, and radiology. In addition, the most recent information relating to a number of new pharmaceutical and chemical preparations is incorporated, and recent progress in vaccine therapy, cancer research, trypanosomiasis, and the treatment of tuberculosis is noted. The results of the chemical and bacteriological inquiry into the value of disinfectants undertaken by *The Lancet* commission are summarised.

The above is a brief outline of the extent of the revision in so far as it is of direct interest to the medical practitioner, but it may be added that throughout the book there is evidence that the authors have scrupulously followed the medical literature of the past two years. Alterations which enhance the usefulness of the book to pharmacists are by no means inconspicuous. Details are given of about a hundred more patent or proprietary medicines than in the last

edition. The authors have indicated by means of signs the part of the poison schedule in which each poison falls; this is an innovation which will be welcomed by retail dealers in poisons, in view of the exacting nature of the Poisons and Pharmacy Act, 1908. Since the last edition was published, new issues of various foreign pharmacopœias have appeared, and these have been utilised where necessary in the preparation of the fourteenth edition.

The "Organic Analysis Chart," which is published as a supplement, is intended to assist the analyst in the recognition of a number of organic chemicals, both natural and synthetic, used therapeutically. This chart gives the results of the examination of more than three hundred substances, and is the outcome of work conducted in Mr. Martindale's laboratory. It is a useful addendum to a book which is indispensable to practitioners of medicine and pharmacy.

A FISHERMAN'S TALES.

An Open Creel. By H. T. Sheringham. Pp. xii+305. (London: Methuen and Co., Ltd., 1910.) Price 5*s.* net.

MR. SHERINGHAM'S contributions to angling literature are always welcome, and we are glad to find that he has published in book form—or, more accurately, has worked up with other materials into a book—some of his contributions to *The Field*. No one need hesitate to look into the "Open Creel"; they will find plenty of fish, some hundredweight and a half of trout, nearly as heavy a bag of salmon, and chub, pike, and bream by the stone. In the preface we are promised that we shall find no plethora of fish in the succeeding essays, and Mr. Sheringham would not have himself regarded as an over-successful angler; to the ordinary reader he certainly seems successful beyond the wont of fisherman, but success in angling, as in other walks of life, is seldom undeserved, and it is with interest that we look for its explanation in our author's own account of his adventures. This is to be found, we venture to think, in his persistency, and his advice to others is to persevere; he who would come home with a heavy basket must needs set forth "with patience and perseverance and a bottle of sweet oil," as the snail went to Jerusalem. Yet it was his oil bottle that so tried Mr. Sheringham's patience that it came within a little of ending an honourable career in the Coln at Bibury.

It would be invidious to select for praise any one essay in the book. "The Float" is excellent, so, too, are the accounts of "Some Kennet Days," and the obituary notice of "Two Colne Trout," and so are many others. Perhaps it is when he fishes for coarse fish that Mr. Sheringham is the best company; such fishing is a more leisurely pursuit, and leaves more time for contemplation and for those digressions into the byways of angling that show him at his best. Sometimes when dry-fly fishing he tends to become a mere compiler of lists of dates and waters, flies and weights of fish, yet he is never wearisome, and has a most amiable weakness for Wickam's Fancy. Did fly fishing give him leisure for contemplation, Mr. Sheringham might meditate upon the problem thus presented; we cannot help thinking that a man's character should be reflected in his taste in flies, and that he who loves Wickam's Fancy must be a happy and contented soul and a good companion at the water's side. At any rate, we have found him good company in print, and recommend others to see if they cannot do likewise.

L. W. B.

OUR BOOK SHELF.

The Photography of Moving Objects and Hand-Camera Work for Advanced Workers. By A. Abrahams. Pp. 153. (London: G. Routledge and Sons, Ltd., and Dawbarn and Ward, Ltd., n.d.) Price 1*s.* net.

MR. ABRAHAMS has been known during the past few years as a very successful photographer of moving objects, especially those in rapid motion, and in this volume he describes his methods freely and fully. He illustrates his experiences with more than forty pictures, which are well reproduced, and these, if nothing else were known of Mr. Abraham's work, would demonstrate his right to speak with authority. After chapters on apparatus, exposure, development, and so on, he deals with the photography of railway trains, athletics, rowing, football, cricket, lawn tennis, horses, divers and swimmers, golf, common objects, winter sports, special subjects, and press photography, giving apparently all the practical details that can be given in a book.

It is of interest that Mr. Abrahams prefers pyrogallol with sodium carbonate and sulphite as developer, in spite of all the new reagents that have been introduced, and that he actually blames metol as the cause of a modified instead of a full success. He advocates swinging the lens when necessary to get better definition of details at various distances from the camera, and justifies his advice by means of at least one example. But when he says, "if you cannot swing the back why not swing the lens," he appears to support the common idea that the one is the equivalent of the other. There is, of course, the radical difference that swinging the lens moves the axis of the lens to a different part of the plate, while swinging the back does not. There is one other common error to which the author appears to lend support, when he says that the shutter-blind "should be really *in the focal plane*"; an obvious impossibility, because the plate itself is there.

Der Sternenhimmel. By Prof. J. D. Messerschmitt. Pp. 195+xiii plates. (Leipzig: Philipp Reclam, Jun., n.d.) Price 1.75 marks.

THIS little book is another well-meant attempt to interest the public in astronomical phenomena by describing in simple language some of the results obtained by continued observation. The general appearance of the sky and the changes produced by the diurnal rotation and annual revolution of the earth about the sun come under notice. Separate chapters are added on parallax and aberration, the precession and nutation of the earth's axis, and the variation of latitude, which last seems a small matter to introduce into a work that can only aim at presenting the more conspicuous features. The several planets are described, their general appearance and motion, and a few remarks are added on comets and meteors.

In the section devoted to the stellar system, the usual information is given concerning double and variable stars, clusters, and nebulæ, proper motion and the movement of the solar system in space. The ground covered is that with which we have been made familiar by many similar works, and it is not a little difficult to justify the appearance of another treatise

on popular astronomy, however accurate it may be in detail. No doubt it is always difficult to know what to omit when space is severely limited, but if the book is to attract the attention of those who are unacquainted with astronomical literature, we suggest that the object would be more likely to be attained if the author had devoted some space to the methods and results of spectroscopic observation. By practically ignoring this large section, he has neglected perhaps the best means of exciting the scientific imagination and awakening an intelligent curiosity in celestial phenomena.

Introduction to Physical Chemistry. By Prof. H. C. Jones. Pp. xv+279. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 1.60 dollars net.

IN this book the author gives a rapid sketch of what is ordinarily known as physical chemistry. Compared with other books of its kind, the result can scarcely be described as satisfactory. The author has tried to cover too much ground in the allotted space, with the result that much of the information is of a fragmentary character. The book is evidently intended for junior students, but it is doubtful whether they would really get any grasp of fundamental principles from such a highly condensed account of physical chemistry.

There are many places where the author's statements are vague, if not erroneous. For example, when discussing solids, he says, "The density of solids is somewhat greater than that of liquids, and much greater than that of gases. This is just what we should expect, since the solid state represents matter in its most condensed form." The second sentence is quite misleading. Again, "Ozone seems to be stable below 200° and above 1000°." Prof. H. C. Jones is a zealous and energetic worker in the field of physical chemistry, and the reviewer would like to have been able to accord this book a hearty welcome. As it is, he feels bound to say that, although it may serve a useful purpose, there are, in his opinion, better works of a similar character already in existence.

Preliminary Physiology. By W. Narramore. Pp. xix+220. (London: Methuen and Co., Ltd., 1910.) Price 3s. 6d.

THIS little book will be mainly useful to school teachers and to junior students preparing for the first-stage examinations of the Board of Education. This class of reader has but little preliminary anatomical knowledge, and the bulk of Mr. Narramore's book is occupied with filling up this gap. There are many other excellent books of the same nature, but the chief merits of the present volume are—(1) it is correct so far as it goes, and it is admittedly of the most elementary nature, and (2) it is provided with excellent illustrations. The author recognises that books and pictures will never teach properly even the elements of an experimental science, and insists that practical work must accompany the course. One can only hope that this expression of opinion will bear fruit. So far as one's experience of the schoolmaster goes, it is just that practical element in his scientific training which is usually conspicuous by its absence.

W. D. H.

The Invicta Table Book. By J. W. Ladner. Pp. 18. (London: George Philip and Son, Ltd., n.d.) Price 2d.

GRAPHIC representations of the multiplication tables and of the commoner weights and measures—including the metric system—are provided, and these should prove very useful in schools where the compiler's number scheme is adopted.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Jodrell Laboratory at Kew.

THE award of a Royal medal to Prof. F. O. Bower for his long-continued researches in the vascular cryptogams suggests to me that it may not be inappropriate to put on record an anecdote in our scientific history in the last century.

In the fourth report of the Commission on Scientific Instruction and the Advancement of Science it was recommended (paragraphs 57 and 154) "that opportunities for the pursuit of investigations in Physiological Botany should be afforded in the Royal Gardens at Kew."

To this the Government paid as little attention as it usually does to the results of the labours of Royal Commissions. But the recommendation was not wholly fruitless, for it induced the late T. J. Phillips Jodrell, a personal friend of Sir Joseph Hooker, to offer to build and equip, at an expense of 1500*l.*, a modest laboratory for the purpose. As stated in the Kew report for 1874, it was originally intended that this should be associated with an extension of the herbarium building which was contemplated at the time; but in consideration of the risk of fire it was decided to have an isolated building contiguous to the propagating department of the establishment.

It was completed in 1876, and was first occupied by Prof. Tyndall for work on the putrefactive changes produced by bacteria, the results of which were published in the Phil. Trans. for the following year.

Since then the stream of research has continued steadily. I "handed in" to the "Botanical Work Committee" appointed by the Treasury in 1900 a list of published papers as the result of work done in the laboratory down to and inclusive of that year, and compiled from copies preserved in it.

The workers in the Jodrell Laboratory are, of course, independent. They are supplied with the material they require, and are at liberty to make use of the Kew library and to consult, if they care to do so, the scientific staff. The nature of the work has therefore been of the most varied kind, and does not represent the influence of any particular school. In this respect the outcome differs from that of an academic laboratory in which research is carried on under the direction, or at any rate with the aid of, the professor.

What I think is worth noting is that, of those who have worked in the Jodrell Laboratory during the fifteen years from 1876 to 1900, no fewer than six have subsequently received the Royal medal. I do not mean to say that it has been in each case wholly earned at Kew, but it is I think clear that the work done there has contributed to the result.

The following are the names, with the general scope of the research and the date of the award:—Burdon Sanderson, electromotive properties of Dionæa, 1883; Marshall Ward, embryology and mycology, 1893; Gardiner, continuity of protoplasm, 1898; Horace Brown, assimilation of carbon, 1903; Scott, fossil botany, 1906; Bower, morphology of vascular cryptogams, 1910. To these may be added, making in all seven medallists, the Davy medal awarded to Schunck in 1899, in part for his researches on chlorophyll.

When one considers the names the results are not surprising, and though Kew enjoys some measure of prestige from being associated with them, that association is to a large extent accidental, at any rate limited to affording facilities. But some conclusions may be drawn. In the first place, the prevision of the Royal Commission is amply justified. In the next place, Phillips Jodrell, were he alive, would have every reason to be satisfied with the outcome of his generosity. But there is a further and more important point. I do not contend that the work I have enumerated was necessarily bound up with the Jodrell Laboratory in the sense that it could not have

been accomplished elsewhere, as, indeed, much of it has been continued. Of course, the medallists were all picked men, who did not lightly embark on research demanding much time and labour without a good deal of previous consideration. I think it may be fairly concluded that the provision of facilities with a sympathetic atmosphere may have operated as a determining influence. The final moral of the story may be summed up as the "open door."

And this applies elsewhere. The mathematician only requires his study. The physicist and the chemist are rarely at a loss for opportunity of research. But the position of the biologist is different. He must go to his material. Such institutions, therefore, as the Rothamsted Experimental Station, the Plymouth Laboratory of the Marine Biological Association, and the Biological Station at Naples, are peculiarly deserving of public support. And I think the story of the Jodrell Laboratory affords tolerable ground for the presumption, if, indeed, other experience did not afford it, that the generosity of those who have money to spare will not be fruitless in results if extended to institutions of the kind.

I cannot, however, omit to notice one piece of devoted service to the interests of the laboratory which, of its kind, is almost unique. A quarter of a century ago the Government looked with more indifference on research than happily it does at present. It merely acquiesced, with little interest, in a laboratory being provided at Kew from private funds. It was hopeless at the time to obtain for it any public financial support. Posterity will almost think it incredible that from 1892 to 1906 Kew should have had to owe to the present president of the Linnean Society, Dr. Dukinfield Scott, the unpaid performance of the duties of keeper. Such unrequited devotion has scarcely received the recognition it deserves. Fortunately, the utility of the laboratory as a necessary element in the Kew establishment has become sufficiently evident, and the keeper is now a member of the paid staff.

Witcombe. W. T. THISELTON-DYER.

Eel-larvæ (*Leptocephalus brevirostris*) from the Central North Atlantic[1]

IN a previous article in NATURE (November 10) I have given some information about the expedition executed by the steamer *Michael Sars* in the North Atlantic, from April to August this year, under the superintendence of Sir John Murray and myself. As would be seen from that article, the expedition crossed the Atlantic twice, first from the Canaries to Newfoundland, and then from Newfoundland to Ireland. During this cruise many hauls were made with pelagic tow-nets and trawls. It is characteristic of the manner of work that many nets and trawls—as many as ten—were towed simultaneously during several hours at each station. The nets and trawls were fixed on the wire as follows: one at the surface, the others at 100, 200, 300, 600, 1000, 1500, 2000, 2500, and 3000 metres. The very considerable number of pelagic forms captured is now being examined. The material includes several hundred Leptocephali belonging to many different species. Among these are forty-four larvæ of the common eel (*Leptocephalus brevirostris*). The localities where these were found are so interesting that a preliminary note may be useful, as suggestive for further investigation.

The accompanying chart (Fig. 1) shows the stations at

FIG. 1.—Chart showing places where eel-larvæ were found, and the number caught.

[1] Communication from the *Michael Sars* North Atlantic Deep-sea Expedition, 1910.

which eel-larvæ were found, the figures indicating the number of larvæ caught at each place. The chart shows the existence of eel-larvæ over the greater part of the North Atlantic between North Africa and North America. The excellent Danish investigations planned by Dr. C. G. Joh. Petersen, and carried out by Dr. Johannes Schmidt, succeeded with Dr. Petersen's young-fish trawl in catching eel-larvæ over depths mostly of 1000 metres along the continental slope from Shetland to Gibraltar. On the American side, larvæ of the American eel (*Anguilla chrysypa*) have already been found over the continental slope off the United States. The catches made by the *Michael Sars* now have this particular interest, that they prove the distribution of the larvæ, not only on the slopes, but also in mid-ocean over the greatest depths, both over the deep eastern and western basins and over the Azores ridge separating them.

According to their length, the larvæ may be divided into two distinct groups, one including specimens of 41 to 60 mm. in length, the other those of 66 to 82 mm. (see Fig. 2). All the specimens belonging to the first group, twenty-one altogether, were found at the stations south of the Azores, marked by a cross, and all those belonging

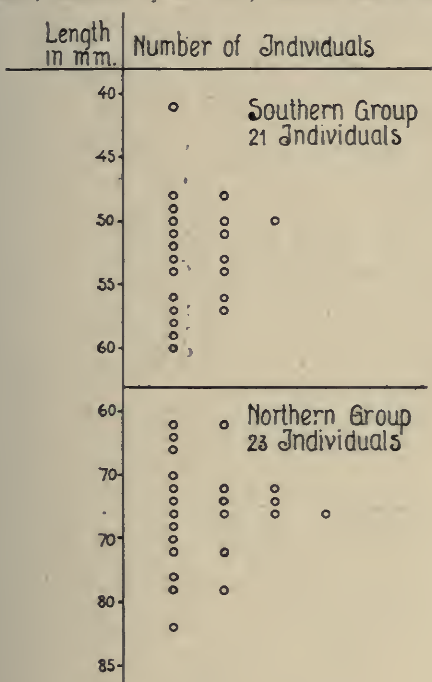

FIG. 2.

to the group of larger individuals were caught at the stations north of the Azores, marked by a circle. In order to control the determination of the larvæ, my assistant, Mr. Einar Lea, has counted the myomers of all the larvæ, and the results are given, for both groups separately, in Fig. 3. All the individuals—of either group—have a number of myomers not exceeding the limits, 111 to 119, given by Dr. Schmidt as characteristic of the larvæ of the common eel (*Leptocephalus brevirostris*). They are thereby distinguished from the larvæ of the American eel (*Anguilla chrysypa*). For the larvæ of the latter Eigenmann and Kennedy give the number of myomers as 105 and 108, and Dr. Schmidt has, by counting the vertebræ, fixed the limits at 104 and 110.

The larvæ of the common European eel previously found by Dr. Schmidt in the North Atlantic were all either full-grown leptocephalic larvæ or in subsequent stages of transformation. Dr. Schmidt describes five different stages. All the larvæ found by the *Michael Sars* north of the Azores belong to one or other of these stages. Outside the continental slope no larvæ of the transformation stages were found, but only full-grown leptocephalic larvæ corresponding to Dr. Schmidt's stage 1. This holds good both for the larva found in April in the Bay of Biscay and for the larvæ found in July between Newfoundland and Ireland. On the continental slope off the British Isles, however, larvæ in transformation stages (Schmidt's stages 2 and 3) were found.

The larvæ found by the *Michael Sars* south of the Azores are all smaller than the full-grown leptocephalic

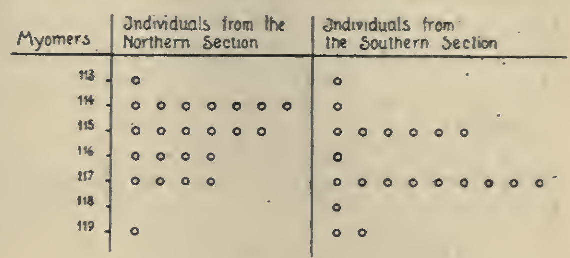

FIG. 3.

larva. I understand them to be stages in the development from the ovum to the full-grown larva. All have teeth which in every essential correspond to those characterising stage 1, as described by Dr. Schmidt. I must therefore consider the larvæ caught south of the Azores to be younger than any before found.

So far, no other stages have been discovered among the materials secured by the *Michael Sars*. More material is therefore needed to give a full explanation of the facts stated above. As, in the numerous Danish investigations and in all the hauls made by the *Michael Sars*, no single specimen belonging to the youngest stages has been found in the area north of the Azores, the conclusion seems natural that the spawning area of the eel must be sought in the southern central part of the North Atlantic. However, the spawning area can only be located by the evidence

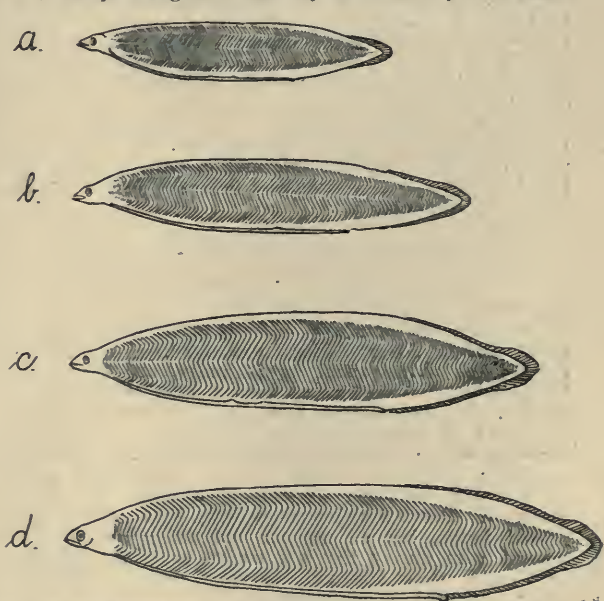

FIG. 4.—Eel-larvæ found by *Michael Sars*; *a–c*, caught south of the Azores; *d*, north of the Azores; *a*, the smallest larva found; *d*, a full-grown larva as the youngest previously found. All the figures are copied from photographs. Nat. size.

of ova. So long as the eggs have not yet been discovered the spawning area must also be considered as unknown; but it is natural to look for it in the neighbourhood of those localities where the youngest stages have been found. The discovery of the ova would not only give information about the geographical position of the spawning area, but also about the ages of the different larvæ hitherto found. It may then be possible to understand the distribution of the different stages—the youngest south and the eldest

north—as a drift with the currents. The negative fact that none of the smaller larvæ have appeared north of the Azores, and none of the larger ones south, seems to favour such an explanation. The further fact that none of the transformation stages, previously found so abundantly on the continental slope, were found in mid-ocean supports the same view. Nevertheless, I consider it dangerous to form any definite opinion from negative facts concerning such vast ocean expanses, where so few investigations have as yet been made.

As a provisional working hypothesis I should be inclined to regard the continental slope as the area where the transformation of the larvæ takes place, and the southern central part of the North Atlantic ocean as the probable spawning area of the eel.

Fig. 5 gives information as to the depths at which the *Michael Sars* caught the eel-larvæ. The youngest specimens were mainly found by towing a net with 100 metres

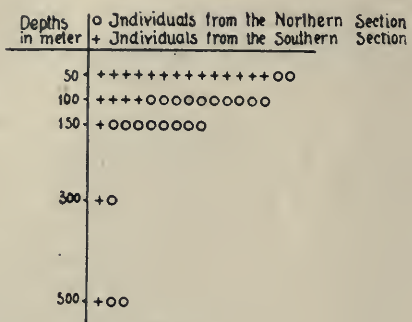

Fig. 5.

of wire out, or in a depth of about 50 metres. The eldest stages were found in nets towed with 200 metres of wire out, or at a depth of about 100 metres. The *Michael Sars* employed for these depths mostly silk nets with mouths of 1 m. in diameter, and no trawls. Otherwise larger catches of eel-larvæ might have been procured. I should recommend that future investigators look for the eggs and the smallest larvæ from the surface down to 100 metres, say between the Azores and Bermudas, in winter. I hope that this information will in this way be found useful.

Bergen, November 7.

Are Mules Fertile?

In the *Nuevo Mundo* of Madrid for October 27 it is stated that a mule, belonging to Don Carlos Gimenez, of Argamasella de Calatrava, recently gave birth to a foal. From India, South Africa, and America reports have reached the writer about fertile mules, but in no single instance has the evidence of fertility been altogether satisfactory. In the present case the information thus far submitted is very meagre. Nothing is said about the breeding of the reputed parent of the foal. She may be a she-ass with the conformation of a mule, or a mule in milk which succeeded in stealing a mule foal from a mare. A Przewalsky-horse hybrid bred at Penycuik proved fertile, but all the ass and zebra hybrids experimented with during the last twelve years proved sterile. The male zebra-horse hybrids were sterile because they never succeeded in maturing perfect sperms. The hybrid "Romulus," *e.g.*, had all the instincts of a pony stallion, and, so far as one could judge with the naked eye, he was capable of getting foals. When, however, a microscopic examination was made, it was ascertained that the sperms were quite or almost tailless—at the most the length of the flagellum was never more than three or four times the diameter of the head, and it was immobile. Why female mules are infertile has not yet been determined.

Sterility in birds seems sometimes to be due to structural changes in the germ cells induced by in-and-in-breeding. It is conceivable that similar changes may sometimes result from intercrossing. It must be admitted that the photograph reproduced in the *Nuevo Mundo* supports the view that the Calatrava foal is a mule, and that the reputed mother is also a mule.

But further and more definite information is wanted before a decision can be arrived at.

J. C. Ewart.

The Origin of Dun Horses.

The cases quoted by Prof. Cossar Ewart from Mr. J. B. Robertson in Nature of November 10 would be good evidence against the theory that every dun horse must have at least one parent dun or grey if the data in the Thoroughbred Stud-book were absolutely trustworthy. This they are not, and all the cases quoted by Prof. Ewart have in them a very considerable element of doubt. Let me indicate these elements by placing the cases quoted in one column, in reversed chronological order, and the necessary remarks in another column parallel.

Cases Quoted.	*Remarks.*
Bay-dun filly, foaled 1907, dam, Unexpected.	This filly is registered "b. or dun."
Dun colt, foaled 1897, dam, Lobelia.	This colt is registered "b. or dun."
Dun filly, Sarah Curran, foaled 1892, dam, Cellulites.	In vol. xvii. Cellulites' foal of 1892 was said to have died, but in vol. xviii. the alleged dead foal becomes Sarah Curran.
Light dun filly, foaled 1886, dam, Danseuse.	This filly is registered "bay."
Dun or chestnut filly, Saneta, foaled 1884.	The breeder had doubts as to this filly's colour.
Dun filly, foaled 1829, dam, Octavia.	This filly died when two days old.
Dun filly, foaled 1763, dam, Miss Thigh.	This filly had eight foals the colours of which were registered, and not one was dun.
Dun colt, foaled 1730, dam, Young Kitty Burdett.	This colt's sire was grey.

The last case quoted is the mare Silverlocks, from which nearly all the duns in the Stud-book are descended. Silverlocks is credited with five foals, the first of which was foaled in 1738, and four of these were dun. Three of these four were by a bay or brown horse. So Silverlocks herself was presumably a dun. The Stud-book assumes that this mare Silverlocks was identical with a chestnut mare Silverlocks foaled in 1825. Either the 1825 Silverlocks was a dun, not a chestnut, or the two mares were different animals.

Royal College of Science, Dublin, November 15.

The Cocos-Keeling Atoll.

In stating the depths to which the bores in the Funafuti lagoon were carried, and in drawing his deductions from them, the reviewer (Nature, November 10) has fallen into a very curious error. He states that the first bore was driven to a depth of 41 fathoms, and the second to nearly 36 fathoms, but he overlooks the fact that he is giving the measurements from the surface of the lagoon water, and not from the lagoon floor.

The bores were started in 101 feet of water at low-water spring tide, and therefore, of the 41 and 36 fathoms mentioned by the reviewer, the top 17 fathoms in each case consist of nothing but lagoon water. The actual bores made into the lagoon bed penetrated no more than 24 and 19 fathoms respectively, or, as I pointed out in my last communication, a maximum of 144 feet.

F. Wood-Jones.

My depths of 41 and 36 fathoms were not intended in any way as a correction of Mr. Wood-Jones's letter. The important point is that lagoon débris *only* occurred above 27 fathoms; there was 10 fathoms of it. Below this depth we get coral rock.

It is a long time since any discussion has been held in this country on coral-reef formation, while much work

has been done during the last decade. I suggest that a public discussion, such as that on "The Origin of Vertebrates," held at the Linnean Society last session, would be valuable.

The Reviewer.

In our work in Challenger Office in connection with deep-sea deposits, we are very much impressed with the fact that solution of calcium carbonate is going on in the ocean, not only at great depths, but at all depths from the surface to the bottom wherever dead organisms which secrete carbonate of lime are exposed to the action of the sea water, as was recognised and insisted on by Semper, Murray, Agassiz, and others. We are therefore much interested in the discussion going on in Nature regarding solution in the lagoons of atolls.

Mr. Wood-Jones considers that there are no actual proofs of solution in the lagoons of atolls, but, at the same time, admits the deposition of calcium carbonate.

The quantity of calcium carbonate present in solution in normal sea water is very small—only 0·12 gram per litre for water of specific gravity 1·026—and *no* precipitate is obtained on allowing it to stand for any length of time. When, however, sea water has remained for some period in contact with calcium carbonate it may take up a greater amount (up to 0·649 gram per litre). The solution is then supersaturated, and, on being allowed to stand, calcium carbonate is deposited in the crystalline form, and the deposition may go on until the solution contains less than is normally present in sea water.

The first condition, therefore, for precipitation is that *more* calcium carbonate than is normally present should pass into solution, and this can only occur when the sea water is in contact with a calcareous deposit for some time.

Would Mr. Wood-Jones say where the calcium carbonate which is precipitated in the crystalline form in the interstices of the massive corals in the lagoons comes from, for it is certainly not from the normal sea water which reaches the reefs from the open ocean?

It would appear that Mr. Wood-Jones's arguments against Sir John Murray's theory go rather in support of it.

Madge W. Drummond.

Challenger Office, Villa Medusa, Boswell Road, Edinburgh, November 17.

The Flight of Birds against the Wind.

In an interesting article (Nature, November 10) upon bird migration and Mr. Power's recently published "Ornithological Notes," Sir T. Digby Pigott expresses surprise at the latter's conclusions that in the large autumnal migrations the birds invariably fly "almost directly against the wind even when it approaches a stiff breeze."

My observations on the flight of gulls during south-west gales off this coast lead to the conclusion that these birds during their aërial gyrations either face the wind or fly obliquely across the current. They very rarely fly, and, I believe, never soar, with the wind behind them. Perhaps less muscular energy is necessary in the former than in the latter case. Fish in rapid rivers, when not actively moving, according to my experience remain with their heads upstream.

W. Ainslie Hollis.

Hove, November 15.

THE ACCURATE MACGILLIVRAY, ORNITHOLOGIST.[1]

"THE accurate MacGillivray" is Darwin's designation of the subject of this notice, and "ornithologist" is the title which, when twenty-three years of age, he himself presaging his own powers, declared it would go hard with him if he did not merit.

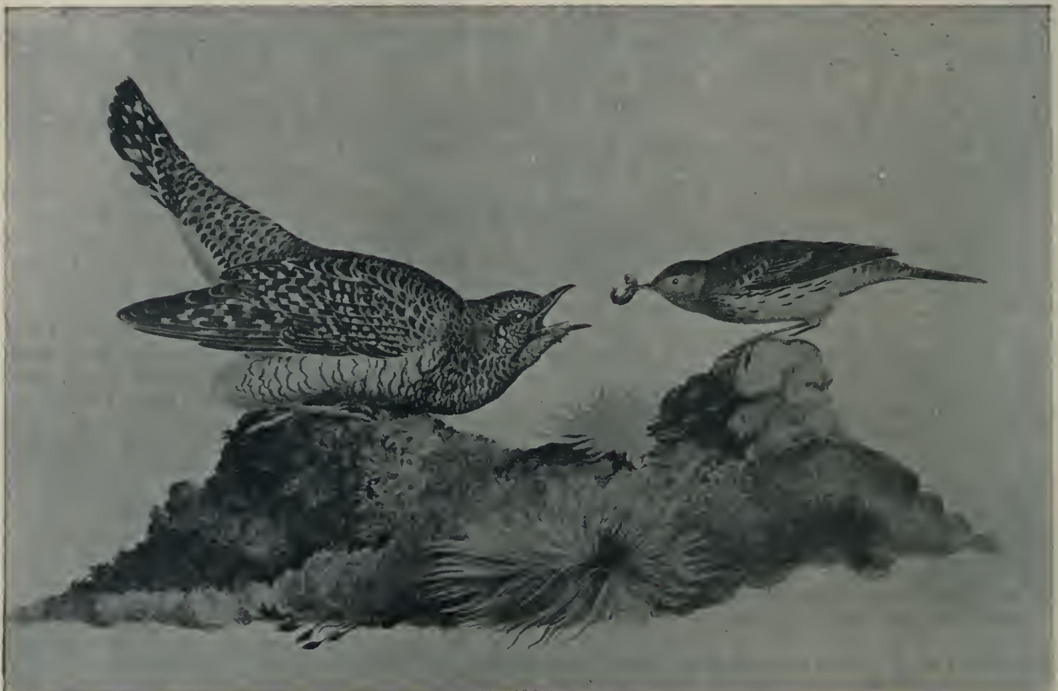
Who MacGillivray was does not require to be told to the ornithologist conversant with the literature of his subject; but the general reader and the superficial bird-man have probably never heard his name. Yet that he was "the greatest and most original ornithological genius save one . . that this island has produced," is the verdict of so distinguished an ornithologist of our day as Newton. Why MacGillivray's biography should have tarried until his ashes had been fifty-eight years in the tomb is hard to understand, except probably that, born before his time, his contemporaries failed to perceive the genius of the man, or realise the pioneer he was.

William MacGillivray, born in Aberdeen in 1796, was the son of a military surgeon who died on the field of Corunna. The story of his self-denying life is that of not a few Scottish students, who, scantily provided with means, have yet by their indomitable will-power and love of learning achieved distinction, honour, and lasting fame. The future ornithologist's boyhood, from the age of three, was spent in Harris, in the Hebrides, where nature is wild and presents herself in many changing and impressive aspects. In the parish school a few miles from his home, he obtained, "under dull scholastic rule," a good elementary education, but his chief and unconscious preceptors were "the solitudes of nature" and "the moaning voice of streams and winds." At the age of eleven he set out for Aberdeen, to prepare, under more advanced tutors, for his entrance the following year into the University there, with a view to his father's profession. He probably on this occasion, as he invariably did at the beginning and end of the various college sessions, walked all the way athwart Scotland from his landing place on the west coast. When twelve years old he entered King's College, at that time the University of old Aberdeen (as then known), which (until 1860) was distinct from Marischal College, the University (junior by a century) of new Aberdeen. Having graduated M.A., when four years older, he proceeded at once to the study of medicine, of which one of the courses was botany, and with it, as he has recorded, he first began the study of nature "which has been particularly fascinating." A year later he took up zoology. His vacations were thenceforth spent in pedestrian excursions over the Highlands and islands, collecting plants and animals, keenly observing and carefully recording every aspect of nature.

It was during this period that MacGillivray acquired his great dexterity with the scalpel, and became so accomplished an anatomist that he was appointed dissector to the lecturer on anatomy in Marischal College. Unable, however, to resist the call of natural history, he relinquished this not uncongenial post in order to devote himself exclusively to his mistress. As one of the means to "further his cognition of these things," he set out on foot from Aberdeen for London *via* Fortwilliam and Ben Nevis—hardly the direct route—to visit the British and other Metropolitan museums, and observe life by the way. Drenched or dry, tired or otherwise, he never neglected at the close of the day to record fully in his journal the valuable notes he had made. After an 837 mile tramp, full of extraordinary experiences, he reached the capital, "satisfied," as he says, "with my conduct"; and not unjustly so, for his expedition had gone far to mature the youthful enthusiast. His study of the various zoological collections in London convinced him that the methods of classification of modern ornithologists were such as he could not accept. Before he returned to Aberdeen he had formed the resolve "to become the author of a new system," which formed the aim of his life thenceforward. In 1819 or 1820, MacGillivray migrated from Aberdeen to Edinburgh, and as he had recently married, it

[1] "Life of William MacGillivray, M.A., LL.D., F.R.S.E., Ornithologist Professor of Natural History, Marischal College and University, Aberdeen. By William MacGillivray, W.S. With a Scientific Appreciation by Prof. J. Arthur Thomson. Pp. xv+222. (London: John Murray, 1910.) Price 10s. 6d. net.

became for financial reasons necessary to accept the post of assistant to Prof. Jameson, who then held the chair of natural history in that city. His beloved birds, however, enticed him away again to the fields for a few years, until in 1831 he received the entirely congenial appointment of conservator of the Museum of the College of Surgeons in Edinburgh. Here he accomplished splendid curatorial and research work—among much else replacing, through his accurate knowledge of living nature, the taxidermal monstrosities he found there by lifelike specimens—wherby his great scientific attainments became very widely recognised. His numerous anatomical investigations were continually supplying material for his new system of classification of birds, which, it was his peculiar merit to perceive, should not, as hitherto, be based on their external characters alone, but on their internal organisation as well. He specially devoted his attention to their digestive organs, undoubtedly too exclusively; but still, his was unquestionably a distinct advance on any method previously attempted. At this juncture he became associated as joint author with Audubon, the American ornithologist, in his "Ornithological Biographies."



Nestling Cuckoo being fed by a Meadow-Pipit. From a drawing by W. MacGillivray reproduced in "Life of William MacGillivray."

In this great work all the technical and anatomical descriptions, and even some of the plates, are MacGillivray's, while Audubon's are the drawings and field notes on the species, of which he had an intimate acquaintance. During this period MacGillivray wrote many other books, but he was busy also with his projected "History of British Birds," the first three volumes of which appeared between 1837 and 1840. The wide reputation he had acquired in Edinburgh won for him early in 1841 the natural history chair in Marischal College, Aberdeen. Into his new duties there he entered with all the enthusiasm and energy of his nature, and with the ardent desire—not unrealised—that through his endeavours "the city might obtain a rank among those distinguished for the cultivation of natural history." So strenuously did he labour for eleven years to this end that he found no opportunity until early in 1852 to issue the fourth volume of his great history. It was published during his stay at Torquay, whither he had retreated "from the blasts of the North Sea," in the hope, which proved vain, of recovering his health, "assailed by disease." In July of the same year, within six weeks after the appearance of the concluding volume, this gifted naturalist and most lovable man passed away, amid the esteem of his scientific contemporaries and the special regard and affection of his former pupils, of whom a small remnant only now survives.

The above personal details are summarised from the first five chapters of this welcome "Life," in which all the available information about his distinguished relative has been brought together by a namesake. The succeeding chapter contains a warm appreciation of MacGillivray's scientific work by the present occupant—the fourth in succession—of the Aberdeen chair, Prof. J. Arthur Thomson, himself an ardent naturalist of the MacGillivray type. The final chapter is devoted to a series of delightful and characteristic descriptive passages from MacGillivray's writings, while a selection of his lifelike drawings from those in the British Museum illustrate the volume, one of which, by the courtesy of the publishers, is here reproduced. A volume on the "Natural History of Deeside and Braemar," found in MS. after his death, was purchased and published privately by Queen Victoria. Ornithologists everywhere will echo the regret expressed by Lady Geddes—whose personal recollections of the professor will be read with special interest—that no portrait of MacGillivray is in existence.

It has been peculiarly gratifying to the present writer to have been requested to bring this biography of MacGillivray under the notice of the readers of NATURE. The deepest pleasures of his own life have been derived from natural history pursuits in many parts of the globe, and he may perhaps be permitted to say that his love for nature was awakened in

early childhood by his father, who imbibed his own interest in zoology and botany as a pupil of MacGillivray, and throughout his life never referred to his old professor without some term of affection. The writer, therefore, has always regarded himself as a grandchild of MacGillivray's influence. It was his fortune afterwards to receive in the same class-room his own zoological training, and to engage in curatorial work in the museum in which many of the specimens were labelled in MacGillivray's handwriting, and some years still later to follow closely the track of the *Rattlesnake*, the naturalist of which was John MacGillivray, the professor's eldest son, and its surgeon Huxley, also the writer's revered master. As familiar to the reviewer, too, is MacGillivray's beautiful handwriting—of which a specimen is reproduced on p. 68 of the "Life"—as if it were that of a member of his own family; for, by a strange chance, one of his brothers had the good fortune, while a student, perhaps about 1865, to rescue for a few pence from a butterer's mean uses a large bundle of MacGillivray's journals. Sad to say, only a few pages ran consecutively, but they were perused with something approaching to veneration. These contained, if memory serves, descriptions of some new species of mollusca; notes of excursions, with zoological and botanical observations—pages, perchance, of the second volume of "A Year's Residence and Travels in the Hebrides," which the "Life" records as lost; memoranda on the conduct and concentration of his pupils, while sitting for their class examination; the names tabulated according to "nations" (natal regions), and to harmony and disharmony in colour of their hair and eyes, with the proportion of successes or failures in these categories. Alas! it is to be feared that these pages have now also gone the way of all things.

It is gratifying, especially to Aberdonians, to find MacGillivray's memory so sympathetically revivified in this volume, and to feel that it will be kept green thereby for the future among his successors in the title of ornithologist.

THE MAORIS OF NEW ZEALAND.[1]

MR. JAMES COWAN has done the student as well as the general reader a service in publishing the material he has personally collected from the *kaumatuas*, the old and learned men of many Maori tribes, for the time is rapidly approaching when very little more can be gathered from the natives. The book is by no means of the monographic kind, but consists of what are virtually a series of essays on different subjects, based entirely on first-hand information and the experiences of a lifetime of sympathetic intercourse with the Maoris.

The subject-matter may be grouped as follows:—The origin and migrations of the Maori and the settling of New Zealand; religion, tapu, omens, and the like; social customs, houses, canoes, tattooing; nature lore, folk-tales, poetry; while the last third is mainly devoted to the Maori in war, intertribal and with Europeans, and to cannibalism.

Comparatively early in the book we find it stated "that the Maori-Polynesian is a brand, though a distant one, of the Caucasian race is now generally accepted." It may be granted that the main stock of the Polynesians had, in the remote past, some relationship with the ancestors of certain peoples now living in Europe, but since then mixture has taken place with other races. A few students of Maori and other Oceanic languages have endeavoured to trace them to a Semitic origin, but there is no likeness between the grammar, and Polynesian and Semitic words are made in an absolutely different way, and there is no sort of likeness in the changes they undergo. The so-called evidence of connection is based only on the resemblances of certain words, but this is a method that could be adopted to prove any other theory. It comes therefore as a shock to read, "Certainly there seems to be adequate evidence to justify us in arriving at these general conclusions: that it was on or near the shores of the Persian Gulf and of Arabia that the ancestors of the Maori-Polynesian lived; that they had racial affinities with the ancient Chaldeans, from whom they gained most of their astronomical knowledge; that they also were blood relations of the Phœnicians, who were the most adventurous of ancient mariners; that they had affinity with the Egyptians, some of whose religious traditions they absorbed" (p. 31). "The coastal people of south-western Asia were from ancient times navigators with a knowledge of the stars; they, and probably the early Egyptians, were amongst the earliest sailors"—[what evidence is there that the Egyptians were ever a seafaring people?] "They coasted down the eastern shores of the African continent, at any rate as far as the Zambesi, and they also visited, and probably partly colonised, Madagascar; this would account for the resemblances between the Maori-Polynesian language and the Malagasy" (p. 35).

The sole evidence for this south-westerly migration

The Korotangi. From "The Maoris of New Zealand."

of the ancestors of the Polynesians is the undoubted relationship of Malagasy with Austronesian languages. Malagasy is definitely related to the Indonesian group of languages, especially the Batta of Sumatra, Ngadju Dayak of Borneo, Sangir, and certain Philippine languages (*e.g.* Tagal), which must be regarded as more primitive than the Melanesian languages or the later Polynesian; but there is nothing Semitic about any of them, and we cannot at present profitably trace the Indonesian-Polynesian stock further back than to the supposed "Gangetic Race" of J. H. Logan, a conclusion to which S. Percy Smith evidently subscribes in his valuable little book, "Hawaiki." Mr. Cowan fortunately deals very little with such problematical questions, and we can feel more at ease when he confines himself to purely Maori ethnology.

There is an interesting account of the several voyages of the historic canoes to New Zealand, and an illustration is given of a carved stone bird, the *korotangi*, or "cying dove," which was brought in the Tainui canoe from the ancient home of the race. Mr. Cowan asserts, and we can well believe him, "it is not of Maori manufacture"; it is $10\frac{1}{4}$ inches long, and "carved with high artistic finish out of a very hard and heavy dark-green metallic stone." Of especial value are the numerous translations of Maori invocations, charms, and poems. The chapter on social life is superficial, and tells us nothing about the real social organisation of the people. The account

[1] "The Maoris of New Zealand." By James Cowan. With numerous illustrations from photographs and drawings. Pp. xxiv+356. (Christchurch, N.Z.; London: Whitcombe and Tombs, Ltd., 1910.) Price 15s. net.

of the *whare-whakairo,* or large communal assembly hall, is of considerable interest. The book is well illustrated, and the note on Maori pronunciation is welcome, but an index is lacking. The get-up of the book is a credit to the New Zealand firm which publishes it.

THE ATTITUDE OF DIPLODOCUS.[1]

SINCE Mr. Carnegie gave a plaster cast of the skeleton of Diplodocus to the British Museum in 1905, he has distributed other copies of this remarkable Dinosaur to the museums of Paris, Berlin, Vienna, and Bologna. A large part of an actual skeleton was also given by the late Mr. Morris K. Jessup to the Senckenberg Museum in Frankfurt. A widespread interest has thus been aroused in the gigantic Sauropodous Dinosauria, and there have been many discussions as to their original form and mode of life.

When the late Profs. Marsh and Cope first obtained nearly complete skeletons of these reptiles, they compared the limbs with those of an elephant, and decided that the creatures must have walked in a quadrupedal manner, with the body well raised above the ground. Considering their immense weight, the position of their nostrils on the highest point of the head, and the feebleness of their dentition, which seems to imply a succulent food, the professors were agreed that the animals must have spent much of their life under water. Prof. Cope also supposed that the long neck, which characterises all the Sauropoda, would enable them to reach the surface to breathe while browsing on water-weeds in a considerable depth of water. It is now generally admitted that the theory of their semi-aquatic mode of life is well founded, and it has been observed that the feeble teeth are not placed in close series, but separated by small gaps, as if they formed a strainer for the food which was taken in. Much difference of opinion, however, has arisen as to the attitude of the limbs.

Messrs. Hatcher and Holland, who prepared the cast of Diplodocus, and Prof. H. F. Osborn, who mounted a skeleton of Brontosaurus in the American Museum at New York, followed Marsh and Cope in arranging the limbs for a quadrupedal walking gait. Dr. O. P. Hay, of Washington, on the other hand, subsequently maintained that the limbs must have been bent, like those of a crocodile, for crawling, and last year Mr. Gustav Tornier, of Berlin, elaborated this theory, publishing a somewhat fantastic sketch of the skeleton as he would arrange it. Prof. O. Abel, of Vienna, has now prepared an interesting summary of all these discussions, and finally concludes that the attitude of Diplodocus and its allies, with which the restorations have made us familiar, is really the correct one.

Prof. Abel begins his paper by deploring the fact that most museums restore the skeletons of extinct animals, partly by hypothetical plaster-work, partly by using the bones of more than one individual, without any clear explanation on the labels. He has, therefore, taken the trouble to state exactly the nature of the materials from which the well-known cast of *Diplodocus carnegii* was made, and he has no serious fault to find with its general composition. It is possible that two or three vertebræ are lacking, and part of the tail may not be sufficiently stout, otherwise there is little to criticise. He thinks that the axis of the head is in direct line with that of the neck; as usual in reptiles, and that the browsing attitude is due to the natural curvature of the end of the neck. He points to the deeply ovate cross-section of the trunk as showing that it is not adapted for crawling along the ground, but must have been lifted during locomotion. He then discusses the structure of the feet in detail, and demonstrates that they are digitigrade, the fore feet more so than the hind feet. As in Iguanodon (of which footprints show the impressions) there must have been elastic pads beneath the toes, and most of the weight of the body seems to have been supported by those below the reduced outer toes. The structure of the digitigrade feet necessitates nearly upright limbs, which would support the trunk and give the reptile a true walking gait. There would be a slight outward bend of the elbow, but otherwise no sprawling attitude. The Sauropoda, therefore, form no exception to the rule, that the extinct Dinosaurs resembled mammals and birds in their habits and movements.

[1] "Die Rekonstruktion des Diplodocus." By O. Abel. Abhand'. k.k. zool.-botan. Ges. in Wien. Bd. v., Heft 3. Pp. 60+Tafel 3. (Jena: G. Fischer, 1910.) Price 2.40 marks.

THE PROTECTION OF NATURE.[1]

"IT is the first time a very comprehensive attempt has been made to do important public service of this character on purely non-partisan lines. . . . It is indeed a great work. We have here the first Commission of the kind ever established by a National Government. . . ." Thus the Hon. Clifford Sifton, chairman of the Commission for the Conservation of the Natural Resources of Canada, at the conclusion of the Commission's first annual meeting, held in January of this year.

The establishment of this Commission is a noteworthy departure, and is actually a method of insuring the future prosperity of the country. Canada is peculiarly amenable to such a step, as large areas of her land are in the hands of the Government, and also peculiarly in need of it. The latter point is obvious when it is remembered that owners of timber property are only just beginning to assimilate the idea of afforestation, that lumbermen are constitutionally destructive, and that forest fires are not an occasional catastrophe, but seasonally recurring and accepted phenomena. In England we hardly realise this last fact, or the destruction produced by a forest fire. The following statement gives a glimpse of the reality:—"The spring fires are not, as a rule, so dangerous to the forests, as they are what we call leaf fires, while the fall fires are soil fires. The leaf fire will run through the woods, and while it destroys a lot of timber, it does not have the same effect as a fire in the fall, because that not only takes the leaves and wood, but it takes the soil as well, and *burns down five feet, so that for a thousand years nothing will grow on that land.*" (My italics.) It appears that railway locomotives cause the majority of these devastating conflagrations.

Destruction without perpetuation has been carried on in other departments. "In the Yukon there are," says Mr. Congdon, "hundreds of square miles where I do not think you could now find a single fur-bearing

animal. They have been absolutely exterminated by hunting; trapping, or by the decrease of the food-supply which occurred in the years 1904-5." An interesting cause is the disappearance of the rabbit. In 1904-5 "some disease smote the rabbits, and they died off by thousands." "In consequence of their disappearance, the animals which fed on them—the fox (the wolf, which need not be counted), the marten, the chief food of which, however, is mice, and other animals—died from absolutely no other cause than starvation." The problem of the conservation of the water supply is curiously bound up with afforestation. For instance, it has been found necessary to conserve the timber on the east slopes of the Rockies in order to conserve the river-heads. "It was shown that the destruction of the timber meant the disappearance of the regular water supply of those provinces, the agricultural production of which is the pride and the hope of Canada."

A list of the committees shows the scope of the Commission. They are seven in number, viz.:—Fisheries, game, and fur-bearing animals; forests; lands; minerals; waters and water powers; public health; press and cooperating organisations. Their reports on the first year's work, the chairman's speech, and the discussions are of unusual interest. Recommendations to Government have already commenced. Such a scheme for the scientific control of the ultimate natural resources of a country must inevitably be adopted elsewhere.

It has, however, one serious deficiency as yet, the absence of any organisation for the preservation of those sites and objects that have no commercial value, but the scientific and artistic importance of which is very great. Such conservation could easily be worked in with the main business. The latest reports of the committees for this special purpose in Germany are to hand. There are official directions giving the least injurious method of picking flowers. Every district seems to be thoroughly looked after and studied by its committee. There are very interesting maps of the habitats of rare plants, and studies of typical fauna, such as that by Dr. Kuhlgatz, on the animal life of the moors in Neulinum. Reference to maps shows that the districts preserved are remarkably numerous. The movement is not merely governmental, but aims at enlisting the sympathetic cooperation of the people. The propaganda is now being extended to the schools, and Prof. Schaefer-Cassel has an eloquent address on the subject. Cases for the "pillory" are recorded, as, for instance, that of a man who in a few years annexed 900 specimens of *Cypripedium calceolus*. This flower, once found near Settle, in Yorkshire, and perhaps in one or two other sites, has now, I understand, disappeared from this country. The same fate will attend many a rare plant, butterfly, or bird, unless we, too, adopt some system of preservation. The *Wild Birds' Protection Act*, it is to be feared, is a dead-letter.

If we had a national commission for the protection of all "monuments of nature," including beauty spots, places interesting for historic or geological reasons, woods, valleys, and hills remarkable for some species of plant, animal, or insect, we should not be a "nation of shopkeepers." But is the United Kingdom too far exploited for a commission for the protection of its natural resources, including its natural history? There would be difficulties in the way, but surmountable difficulties. One very obvious fact presents itself at once—these places of beauty, these habitats of species (by no means useless for the ends of commerce, since they subserve the ends of science), are precisely those which defy culture and would never make it worth while. To make them into natural museums would be a work for which future generations would be more grateful than we can realise. The museum of brick and stone has its uses; zoos and botanical gardens are of no little value; but neither can compare, either for interest or for scientific study, with a reservation. Not only Germany, but Australia, is setting an example here. Dr. Conwentz's book, recently published in England, and an excellent article by Dr. Günther in the *Naturwissenschaftliche Wochenschrift* of August 7 last, give a luminous exposition of the principle and its results.

In time perhaps the world will be full of such spots, where nature may have her Sabbaths and preserve her most interesting children, among whom, last but not least, will be aboriginal varieties of man himself. Is there not a reservation for the tribes of Central Australia?

A. E. CRAWLEY.

AGRICULTURE IN THE DRY REGIONS OF THE BRITISH EMPIRE.[1]

THE ordinary farm crops on which the supply of food-stuffs depends seem to be produced best in regions where the rainfall varies between 20 and 35 inches per annum. Where the upper limit is exceeded in the British Islands, a good deal of pasture is found; on the other hand it is notable that the great wheat-producing districts, the eastern counties, are regions where the rainfall comes nearer to the lower limit. Special agricultural methods become necessary where there is less than 20 inches of rain, as is the case over large areas in Canada, Australia, India and South Africa. These methods fall into two groups: irrigation is required if there is less than 10 inches of rain, while special cultural operations, collectively known as "dry farming," are used when there is as much as 15 or more inches. Between 10 to 15 inches, sometimes the one and sometimes the other method proves the more economical.

"Dry-farming" methods are of great interest to the student of soil physics. Their object is to keep the rain water near the surface of the soil and to prevent loss by evaporation, by surface drainage, and, if possible, by percolation. A remarkable degree of success appears to be attained. An examination of the methods in vogue in different parts of the world shows that all have certain features in common. The land is ploughed up in a rough state and the subsoil compacted directly after harvest or before the rainy season, if there is one; in countries where the rain is unevenly distributed and torrential downpours occur, rather elaborate terracing is arranged to prevent any loss by running off the surface; any streams that form having to follow a sinuous course over the whole field, so that absorption may be as complete as possible. Directly the rain is over, the surface soil is thoroughly stirred, thereby losing a little water by evaporation, but forming a loose layer. The water is thus imprisoned between the compacted subsoil and the thin loose layer of surface soil. The greatest importance is everywhere attached to the maintenance of this loose layer on the top; cultivation is repeated as often as rain has fallen, or whenever for any other reason it is considered the layer has become compact. Incidentally this repeated cultivation has the effect of keeping down weeds, which, if unchecked, would use up a good deal of the water.

In the dry parts of Canada and the United States, where these methods are most highly developed, it is customary to take a crop—usually wheat—once in two years only, leaving the land fallow in the alternate year. It is considered that two-thirds or even more

[1] *Transvaal Agricultural Journal*, vol. viii., 1910.
Agricultural Journal of the Cape of Good Hope, vol. xxxvi., 1910.
"Water Requirements of Crops in India." By J. W. Leather. (Memoirs of the Department of Agriculture in India.)

of the year's rainfall may, under favourable conditions, be stored in the soil for the next year; thus, if only 15 inches fell each year, making a total of 30 inches in the two years, the wheat crop grown during the second year should have moisture available equivalent to 25 inches or more, on which, of course, it should do very well. Unfortunately, the rainfall does not necessarily remain near its average, but fluctuates considerably, and records are not available for many districts; it has occurred in districts where dry farming was considered a great success that the rainfall was, after all, about 20 inches, and ordinary cultivation would have been equally good.

However, the interesting problem is this: What is function of the compact subsoil and the loose surface layer? It is usual to suppose that the compactness of the subsoil facilitates the upward lift by surface tension of water from the permanent water table, but it would seem equally rational to suppose that the compact subsoil retards the percolation of the water. So far as the writer is aware, no crucial experiments have been made that show beyond doubt how far the upward movement of water by surface tension is a factor in ministering to the needs of the plant. That it takes place, of course, is not disputed, but its relative importance is unknown. The function of the loose layer on top, the "mulch," is not settled. It is commonly regarded as a break in the structure of the soil leading to a rupture of the "capillary films" of water. It may equally be a non-conducting layer shielding the mass of the soil from the sun's heat, and therefore lessening evaporation.

Until these problems are solved, little advance can be expected from the scientific point of view, although the practical man continues to effect improvements. The fundamental need seems to be a mathematical analysis showing how water will distribute itself over a mass of particles varying in diameter from below 0·002 mm. up to 0·1 mm., the bulk being below 0·01 mm., and how rapidly any disturbance in equilibrium will readjust itself. The pressing need of work in this direction may be gauged from a perusal of the Transvaal, the Cape, or the South Australian Agricultural Journals; in South Africa alone a considerable part of Cape Colony, the western halves of the Orange Free State and the Transvaal, the whole of the Bechuanaland Protectorate and a considerable portion of southern Rhodesia fall within the "dry lands" area. Some useful practical work may be expected from the newly established dry-land experiment station, but that will only intensify the necessity for a scientific study of the problem.

There is also need of work by the plant physiologist on the effect of insufficient water supply on plant growth. In Dr. Leather's paper data are given showing how much water is transpired by a plant in the production of one pound of dry matter, and on the basis of these figures a table is made out showing how much irrigation or rain water is needed to obtain crops of certain sizes. The values depend on the amount of food-stuff available; less water is needed per pound of dry matter produced in a rich soil than in a poor one. Although there is no direct causal relationship between transpiration and assimilation, the ratios obtained by different observers in various parts of the world are roughly of the same order; thus for barley the number of pounds of water transpired per pound of dry matter produced are:—

Lawes and Gilbert (Rothamsted, 1850)	257

E. J. RUSSELL.

THE CAVENDISH LABORATORY.

THERE is no more pleasant way of spending a week-end than by re-visiting the University Town of Cambridge in term time to meet the old friends and comrades of years gone by, and it was a happy thought that induced the writer of the "History of the Cavendish Laboratory" to choose a Saturday for presenting an edition de luxe of the book to the Cavendish Professor of Experimental Physics.

Saturday, November 12, was a red letter day for all who are interested in the Cavendish Laboratory, for it was the occasion of the assembling of a number of distinguished persons to do honour to the "boy professor" of a quarter of a century ago, who has so amply justified the confidence of the Board of electors in appointing so young a man to a post of such importance. Clerk Maxwell and Rayleigh were not easy men to follow; the standard they had set was a high one, the Cavendish Laboratory had become a prominent institution dependent for maintaining its position and for its further development not only on the scientific reputation of its Director, but on his power to attract the ablest young men of the day.

How far Sir J. J. Thomson has done this was evidenced by the number of distinguished visitors to Saturday's ceremony, among whom we noted: Lady Thomson and her little daughter Joan, Mrs. Sidgwick, the Vice-Chancellor, the Bishop of Ely, the President of Queens' and many Masters of Colleges, Sir T. Clifford Allbutt, Sir Robert Ball, Profs. P. V. Bevan, R. H. Biffen, F. C. Burkitt, Sir George Darwin, Prof. Ewing, Dr. Wm. Garnett, Profs. W. M. Hicks, F. G. Hopkins, B. Hopkinson, Dr. J. N. Keynes, Sir Joseph Larmor, Profs. Liveing, Leahy, Alexander Macalister, Dr. J. E. Marr, Profs. H. F. Newall, W. J. Pope, J. H. Poynting, E. Rutherford, Dr. J. E. Sandys, Mr. Sidney Skinner, the Hon. R. J. Strutt, Mr. H. M. Taylor, Mr. W. C. D. Whetham, Prof L. R. Wilberforce, Mr. C. T. R. Wilson, Prof. G. Sims Woodhead, and Prof. A. M. Worthington.

In the unavoidable absence of the Chancellor, the Vice-Chancellor presided, and declared his position a sinecure in that the speakers needed no introduction.

Dr. Glazebrook, in making the presentation, began by reading a message, contained in a letter to himself, from Lord Rayleigh, Chancellor of the University:—

My interest in the Cavendish Laboratory began with—indeed preceded—its inception, and I had the privilege of the acquaintance of that great genius, the first professor, on whom fell, of course, a vast amount of work in connection with the building and equipment. The laboratory had hardly more than got to work when British science sustained an irreparable loss by the death of Maxwell. My interest then became a responsibility. During the five years from 1879 to 1884 the educational work was greatly developed under yourself and Dr. Shaw, and in research some good work was done. But I must not dwell upon what, no doubt, most of the present students look upon as the dark ages. For six-and-twenty years Sir Joseph Thomson has had the direction, and under him the Cavendish Laboratory has assumed the first place among physical laboratories. By his own researches, pursued with astonishing ardour and success, he has opened up a new world, and, what is in some respects a task even more difficult, he has inspired and trained a number of followers, among whom I am pleased to reckon my own son. Cambridge has every right to be proud of the Cavendish Laboratory, its professor, and his staff.

I will ask you to convey my congratulations to Sir J. J. Thomson. For the future one can wish nothing better than that it should resemble the past.

Dr. Glazebrook, continuing, briefly sketched the history of the Laboratory as contained in the book, which he said was written by men who took part in the events they described.

The book has been written partly in the hope of enabling educated Englishmen who are not physicists to understand the meaning of the work done at the Cavendish Laboratory. . . . It covers a wide range of intellectual qualification from that of the M.B. student to that of the brilliant band Rutherford, Wilson, Townsend, McLellan, Langevin, Richardson, Zeleny, and the others who were research students ten years ago. The Master of Trinity in an eloquent speech a few months ago told his audience he was a dreamer of dreams, and in one dream he pictured a larger university with its portals opened wide and men of many nations and kindred flocking in from all lands to reap the rich harvest of ancient learning or modern science which only Cambridge can furnish, and to carry back to their distant homes the garnered sheaves to feed and fertilise the world. Sir J. J. Thomson has realised such a dream. The new regulations for advanced students passed in 1895 were accepted in large measure through his advocacy, and since that time an ever-increasing stream of men coming from every land has been directed towards Cambridge; the list of those who have carried on researches in the Cavendish Laboratory during the last forty years contains some 250 names; the list of published memoirs covers forty pages. Former students hold important posts in almost every great university; the fact that of the professorships of physics in the colleges of university rank in England all but one are held by Cambridge men shows the wide influence of the laboratory at home. Go where you will, not only in English-speaking lands, to any centre of physical study and you will find one or more who is proud to say he was a research student of the Cavendish Laboratory and a pupil of Sir J. J. Thomson.

As representing those pupils and in the name of the large assembly here present, in the name of the scientific world, I am here to express to you our high appreciation of the services you have rendered to science and to the University, to assure you of the affectionate regard for you personally of all your pupils, and to wish for you and Lady Thomson many years of fruitful activity and continued happiness. Can I do better than repeat the Chancellor's wish—that the future may resemble the past?

It is my privilege to ask you to accept this volume with its record of your great work as some slight recognition of all you have done.

Sir J. J. Thomson responded in a characteristic speech. There was no mention of his own work further than the expression of the wish, which raised a smile on all faces, that he had done more. His speech was an acknowledgment of all he owed to his College, his University, and those personal friends from whom, he said, he had received help without which there would have been no such celebration. He referred to the triumvirate Rutherford, McLellan, and Langevin, and mentioned that one of them had received the Nobel prize. No one was forgotten in the expression his thanks; the demonstrators, the students, the assistants in the Laboratory, were all remembered and many of them mentioned by name. To everyone full appreciation was accorded, and the one person not mentioned, whose work and influence were not alluded to, was the Director of the Laboratory, the Professor to whom all else was due.

The Vice-Chancellor briefly declared the proceedings ended, and passed, "as a business man," to the next item of the agenda, "Cavendish Laboratory Afternoon Tea," an institution of Sir J. J. Thomson, which has accompanied Cambridge Physicists to all parts of the world and, conversation becoming general, the afternoon ended most pleasantly.

S. J. D. S.

MR. W. R. FISHER.

As announced with regret last week, Mr. W. R. Fisher, assistant professor of forestry at Oxford, died on November 13, after an operation. He had not been in good health for some time past, but his death occurred rather suddenly.

Mr. Fisher was born in 1846, at Sydney, New South Wales, where his father was Crown Solicitor, but became afterwards the first Attorney-General of New Zealand. He came to England quite young, and was educated at Cambridge, the home of his father and grandfather, the latter having been a banker in Petty Cury. He joined St. John's College, and took his degree in 1867, being placed 17 senior optime. Soon afterwards he became a mathematical master at Repton School.

In 1869 Mr. Fisher competed for an appointment in the Indian Forest Service, being bracketed first. After the necessary training in forestry, chiefly at Nancy, and partly in Scotland, he joined the Bengal Forest Department in 1872. On the establishment of the Assam Chief Commissionership, in 1874, he was transferred to that administration and remained there until 1878. During that time he started the Charduar Rubber Plantation (*Ficus elastica*), which was extended to an area of about 1000 acres. Mr. Fisher was thus one of the pioneers of artificial rubber plantations. In 1878 he was specially selected for the appointment of deputy-director of the newly-established School of Forestry at Dehra Dun, and he rose subsequently to become the director of the school and conservator of forests of the school circle.

In the year 1889 he came home on furlough, and in 1890 he joined the staff of the School of Forestry at Coopers Hill College. In the year 1905 he went with that school to Oxford, where he became a member of Brasenose College.

Mr. Fisher has left his mark upon forest science and practice. At Dehra Dun he taught chiefly forest botany, and he brought out a volume on plant physiology. After he joined at Coopers Hill, he taught silviculture, forest protection, and utilisation. He joined Sir W. Schlich in bringing out the latter's "Manual of Forestry," of which he undertook the preparation of vol. iv. on "Forest Protection," and of vol. v., on "Forest Utilisation," now in their second edition. Although these two volumes are adaptations of Hess's work on protection and Gayers's book on utilisation, Fisher's books are more than the original works, since he adapted the material to British and Indian conditions. They may be considered the standard works on the two subjects.

Throughout his life Fisher was an active writer, and it would be difficult even to enumerate the many articles on forestry which he published. He was an active member, and president for two years, of the Royal English Arboricultural Society, and editor of the society's *Journal*. After his arrival at Oxford, he started an arboretum of indigenous and exotic trees on land belonging to Magdalen College.

During his leisure time he advised many British proprietors on the management of their woods, and thus helped forward the question of forestry and afforestation in these islands. He was, in 1907, a member of the Departmental Committee of the Board of Agriculture in Ireland on afforestation, and lately of the committee sitting in London, dealing with agricultural and forestal education in Britain.

Mr. Fisher was a man of very simple character, with a warm heart, and he was universally liked, not only by the students, but also by a large host of friends. He conducted the annual excursion to France, and it was quite touching to see how French

forest officers and subordinates admired and honoured him.

He married, in 1876, Mary, eldest daughter of the late Dr. Briscoe, civil surgeon of Cooch Behar, in Bengal, and leaves one son, a lieutenant in a Ghurka regiment, and two daughters. By his death the Empire loses an enthusiastic forester, who can ill be spared at the present time.

NOTES.

We regret to see the announcement of the death on November 11, at sixty-two years of age, of Prof. Jules Tannery, the distinguished French mathematician.

Councillor Wiehl has just bequeathed, says the *Revue scientifique*, the whole of his fortune, of about a million crowns, to the Bohemian Academy of Sciences at Prague to encourage scientific and technical research.

A short time ago it was suggested that the Eiffel Tower should be used as a station for the daily transmission of time-signals to ocean-going vessels by means of wireless telegraphy. The Paris correspondent of the *Times* reports that this service was inaugurated on November 21 with satisfactory results. In future, time-signals will be sent out twice daily, at 11 a.m. and 12 midnight. Three signals will be made on each occasion at two-minute intervals. The morning transmission will not, however, take place on Sundays and holidays.

The Earl of Stair has accepted the presidency of the Royal Scottish Geographical Society in succession to Prof. James Geikie, F.R.S., who has held the office of president for the last six years. The anniversary meeting of the society was held on November 11, and was addressed by Sir John Murray, K.C.B., F.R.S., who chose for his subject "The Deep Sea." Before the address Prof. Geikie was presented with the society's gold medal in recognition of his distinguished services to geographical science, and Sir John Murray with the Livingstone medal in recognition, not merely of his prolonged and valuable oceanographical research, but also in commemoration of the completion of the great national work "The Bathymetrical Survey of the Fresh-water Lochs of Scotland."

In the interests of precision in scientific diction, a correspondent asks that the familiar expression "thunder and lightning" should be inverted in accordance with the natural sequence of cause and effect, and become "lightning and thunder." He adds:—"I never could grasp how the confusion originated, considering that, in agreement with the transmission of light and sound, the flash is seen before the thunder is heard."

The eighty-fifth Christmas course of experimentally illustrated lectures adapted to a juvenile auditory, to be given at the Royal Institution by Prof. Silvanus P. Thompson, F.R.S., promises to be of exceptional interest. The subject is "Sound, Musical and Non-musical." The dates and subjects of individual lectures are:—1910, December 29, production of sound; December 31, transmission of sound; 1911, January 3, reception of sound; January 5, combination of sounds; January 7, registration of sounds; January 10, reproduction of sound.

At a meeting of the executive committee of the British Science Guild, held on November 16, on the motion of Mr. A. Moseley, C.M.G., it was decided to form a special combined education committee to deal, in the first instance, with education of the governing classes of England. It was resolved to defer the circulation of the synchronisation report until a later date. It was decided to consider further the reduction of the rate of postage on scientific literature. It was also suggested that the annual meeting should in future be held in the month of April, and that the annual dinner should, if convenient, be held on the same day.

We regret to announce the death, at sea, at the age of thirty-one, of Mr. Richard Froude Tucker, Archæological Surveyor of the Northern Circle, India. Mr. Tucker held the post of curator of the Delhi Museum, and the catalogue of the archæological collections deposited there was recently prepared by him in collaboration with Dr. J. Ph. Vogel. Appended to this catalogue is a memoir by Mr. Tucker on the elephant statues at the Delhi Gate of the Delhi Fort. The untimely death of this promising archæologist is a severe loss to antiquarian research in India.

During the summer of this year excavations were carried on, under the superintendence of Dr. Felix Oswald, at the site of the Roman station of Margidunum on the Fosse Way, midway between Leicester and Lincoln. Some local pottery, Samian ware, coins of Victorinus, Carausius, Constans, and Eugenius, dated between 265 and 395 A.D., have been discovered. The main feature of the finds was the relative abundance of iron objects, such as swords, knives, a bolt of a spring-lock, rings, and nails. A skeleton of an old man and three infants was associated with bones of the Celtic ox (*Bos longifrons*) and other domesticated animals. These antiquities have been deposited in the museum at Nottingham Castle, where it is hoped they may form the nucleus of a Romano-British section.

The Rome correspondent of the *Times* announces that a decree was published on November 20 creating a commission to examine the view that pellagra is produced by a protozoal infection conveyed by an insect, and to formulate any changes in the existing law of protection that may be considered desirable. The commission consists of nine members, all doctors with the exception of Prince Teano, deputy, who was chiefly instrumental in directing the attention of the Italian Government to the work of the English Pellagra Investigation Committee. An article upon the investigations made by Dr. Sambon for this committee appeared in Nature of October 27.

On November 12 an extension of the natural history section of the Hull Public Museums was opened by Mr. T. S. Taylor, Mayor of Hull. In the ornithological section of the museum there is an unusually extensive collection of British birds. The extension consists of three large rooms, the largest of which is occupied by a collection of British birds containing more than 900 specimens. In the second room is a collection of local mammals, including the group of otters, badgers, stoats, weasels, and so on. The third room contains a collection of skeletons—animals and birds. The museum is fortunate in having been presented with the collection of birds formed by the late Sir Henry Boynton. This collection consists of about 200 cases containing 450 birds.

Attention has already been directed in Nature to the scheme of the British Empire League for the erection in London of a memorial to Captain Cook. We are glad to notice that the secretaries of the Royal Society have written to Lord Brassey, the honorary treasurer of the fund, expressing, on behalf of the Royal Society, approval of the scheme, and enclosing a subscription of twenty-five guineas from the society. Their letter includes the following paragraph:—"We are instructed to express the gratification of the Royal Society that public opinion has at

length taken form in this direction, to the extent that there is now a prospect of a memorial which shall be not inadequate to the merits and renown of this great explorer. As the circular issued by your committee states, the Royal Society was closely connected with the initiation of these famous voyages, with the selection of Captain Cook to the command, and with the working up and publication of the results of the expeditions. Many of its Fellows, including Sir Joseph Banks, one of Cook's companions in his first voyage, afterwards for many years president of the Royal Society, took a prominent part in that work; and the society still retains in its possession memorials of this connection."

UNDER the heading "Earthquakes in the Pacific," the *Times* of November 17 published a statement by Mr. J. J. Shaw, of West Bromwich, that there was evidence the ocean depths of the Pacific are in a state of great unrest. Mr. Shaw said that his seismograph recorded shocks at 8 a.m. on Monday, November 14, and at midnight and between 2 and 3 p.m. on Tuesday, November 15, all at a great distance. In reply to an inquiry as to these reported disturbances, Prof. Milne has sent us from Shide the following records of earthquakes in October and November:—"Although a few small earthquakes were recorded in October, the month was one of earth rest. During the first two weeks of November seismic activity was somewhat pronounced. The dates on which records were obtained, followed by the times of commencement and maximum movement in hours and minutes, were as follows:—November 6, 19.18 and 21.23; November 9, 6.16 and 7.50 or 8.5; November 14, 7.35 and 8.34; November 14, 19.58 and 20.27; November 15, 0.31 and 10.45, 6.1 and 6.21, 7.42 and 7.46, 9.16 a maximum, and, lastly, 14.35 and 15.21. The second of these was the largest, having an amplitude of 7 mm., which means that tiltings of 2·2″ occurred. The time employed is G.M.T. civil, or midnight = 0 or 24h."

AT the first Optical Convention, held in 1905, a permanent committee was appointed, to which was entrusted the task of deciding upon a suitable date for the holding of a second convention, and of taking the necessary steps to initiate it. A general meeting of the committee and of members of the optical industry, representatives of optical bodies and societies, and others interested in optical questions, will be held on Tuesday, November 29, to consider and discuss proposals for the organisation of a second convention. The chair will be taken by Dr. R. T. Glazebrook, C.B., F.R.S., director of the National Physical Laboratory, as chairman of the permanent committee, and all interested are invited to be present at the meeting. The main features of the scheme which the members of the existing executive committee have in view, and the principal questions on which it seems necessary, at this general meeting, specially to invite discussion, are in broad outlines as follows:—(1) an exhibition of optical and allied instruments; (2) the preparation of a catalogue of optical and allied instruments of British manufacture to serve as a convenient work of reference for all users of optical and scientific instruments, not necessarily to be limited to instruments actually exhibited; (3) the holding of meetings for the reading of papers and for discussions and demonstrations on optical subjects; (4) the publication of a volume of Proceedings, in which these papers will be collected together.

WE regret to see the announcement of the death, on November 16, of Dr. J. F. Payne, emeritus librarian to the Royal College of Physicians, and the author of valuable medical works and many other contributions to science. From an obituary notice in the *Times* we learn that Dr. Payne was born on January 10, 1840, and took his degree at Oxford in 1862 with first-class honours in natural science. In 1863 he obtained the Burdett-Coutts scholarship in geology, and in 1865 the Radcliffe travelling scholarship. In accordance with the regulations of the Radcliffe scholarship he went abroad, spending some time in Paris and in Berlin, and proceeding later to Vienna. On his return to this country Dr. Payne was appointed examiner in natural science at Oxford, demonstrator of morbid anatomy and curator of the museum to St. Mary's Hospital. It was about this time that he revised, enlarged, and edited Jones and Sieveking's "Manual of Pathology." In 1871 he went to St. Thomas's Hospital, being appointed lecturer successively in general pathology, materia medica, forensic medicine, and finally on the principles and practice of medicine. About nine years ago he was appointed consulting physician to this hospital. In 1873 Dr. Payne was appointed to deliver the Gulstonian lecture of the Royal College of Physicians, and in later years he gave the Lumleian and the FitzPatrick lectures. In 1879, when the plague was prevalent in Russia, and the college was consulted by the British Government, they appointed Dr. Payne to accompany Surgeon-Major Colvill as commissioners to investigate and report on the disease. He became a Fellow of the Pathological Society in 1869, and was afterwards a councillor, a member of the morbid growth committee, secretary from 1880–2, vice-president from 1888–9, and president in 1897. He was twice president of the Epidemiological Society, choosing for his first inaugural address the subject of "Tuberculosis as an Endemic Disease," and on the second occasion "The History of Epidemiology in England." He was also president of the Dermatological Society, and was vice-president of the Royal Medical and Chirurgical Society in 1906. Dr. Payne was the author of "A Manual of Pathological Anatomy" and "Observations on some Rare Diseases of the Skin," and the life of Thomas Sydenham in the "Masters of Medicine" series.

THE Eugenics Education Society has distributed a special "Poor Law number" of the *Eugenics Review*, which is devoted to the eugenic aspect of Poor Law reform. The number contains a report of a committee of the society appointed to consider the reform of the Poor Law from this particular point of view; reviews by Dr. C. S. Loch and Mr. Sidney Webb, respectively, of the majority and minority reports of the Poor Law Commission; and a most valuable article, by Mr. E. J. Lidbetter, the General Relieving Officer of the Bethnal Green Union, on some examples of Poor Law eugenics. Of the report of the committee, the third section is the most important. Through the kindness of various boards of guardians, the committee has been allowed access to workhouse records, and, where necessary, personal interviews with paupers; three extensive pedigrees of pauperised families are in course of construction, and the most complete of these is now published, the chart being supplemented by a key giving detailed particulars of the cases included. The chart covers five generations, and indicates the intermarriage of five pauper families. Mr. Lidbetter's investigation supplements this report of the committee by some thirteen charts of pedigrees based on his personal investigation. The society and Mr. Lidbetter deserve unreserved commendation for carrying out such researches, which must have required much prolonged and laborious work. It is no reflection on the work if we add that it still remains a most difficult problem to determine, on the

basis of such data, the relative parts played by heredity in the strict sense of the term, continuity of environment, and example. We gather from an accompanying letter that the society finds it impossible, from lack of funds, to proceed with such investigations on any sufficient scale, and urges the formation of a Departmental Committee with power to examine records.

AT the recent conversazione of the Geologists' Association, held at University College, Gower Street, a series of worked flints from the Ipswich district was exhibited. The circumstances in which they were unearthed indicate that they are probably the oldest works of man yet discovered in this country. They are well chipped, deep brown and cream in colour, and several show scratches which may be the glacial striæ imprinted when they formed part of the gravel at the base of a glacier. Technically speaking, they are of pre-Crag age, that is to say, they long precede the Glacial period. Mr. W. Whitaker, F.R.S., who mapped the district for the Geological Survey, is satisfied that they come from undisturbed beds, and that the gravel from which the flints were obtained is of pre-Crag Age. This discovery, if it stands the criticism to which it will certainly be exposed, marks a memorable advance in the prehistoric anthropology of this country.

IN the October issue of *Man* Mr. D. Alexander gives an account of a performance of a Nigerian Punch and Judy show, which in some ways resembles the drama which is familiar to us. A forked stick is thrust into the ground, the performer kneels, and, taking off his black gown, throws it over the stick, the opening for the head of the wearer serving to provide a space for the display and withdrawal of the figures. The conversation between the puppets is carried on, as in the European performance, in a squeaky tone. The place of origin of this play is somewhat uncertain, but there seems to be no doubt that it is an indigenous invention. In the same issue of *Man* Captain A. J. N. Tremearne discusses the system of bull-fighting among the Fulani, a race of cattle breeders in northern Nigeria, who seem to be of Berber origin. In contrast to the conditions of the sport in Spain or Portugal, the Nigerian variety is comparatively tame, no horses being used, the performers being unarmed, and the bulls escaping any kind of injury.

To the *Irish Naturalist* for November Dr. Scharff communicates an article on the whale-fishery which has been carried on by Norwegians during the last three years at Inishkea, and for a rather shorter period at Ely Point, on the Mayo coast. At the former station 124 whales have been taken during the last two seasons, most of these being rorquals, although five black right-whales, of an estimated value of between 1500*l.* and 3000*l.*, were captured in 1908. A single blade of the whalebone of this species is worth about two guineas, and the total yield of this substance may be as much as a quarter of a ton, with a value of about 400*l.*

IN a pamphlet on the distribution and migration of North American shore-birds, issued by the U.S. Department of Agriculture as Bulletin No. 35, Mr. W. W. Cooke emphasises the economic importance of this group. For many years the abundance of larger birds, such as swans, geese, and ducks, caused the waders to be neglected, but with the killing off of the former gunners directed their attention to the latter, which now stand in need of immediate protection. In addition to their value as food, the plovers and some others do valuable service as destroyers of noxious insects, while all the members of the group are of special interest from an æsthetic point of view. Details of the distribution and migrations of the various species form the bulk of the pamphlet.

IN the October issue of the *Irish Naturalist* Mr. A. Williams directs attention to the presence of sanderlings during the last three years on the shores of Dublin Bay throughout July, a month when these birds are generally supposed to be residing in the far north for the purpose of breeding. These July birds are evidently non-breeders—either old or barren—but it has yet to be determined whether they remained in Ireland when the bulk of their kind winged their way northwards, or whether they were the first of the main body to return south. During their sojourn in Ireland these non-breeders undergo a considerable change in plumage. "They have been found with the red colouring entirely absent, and also the soft grey margins of the feathers, which conceal the nuptial plumage in spring, completely worn away, and in some instances the ruddy coloration faded out, causing the birds to present a totally changed and misleading appearance."

THE Manchester Museum is one of the most flourishing of the provincial museums in this country, and its report for the year 1909–10 is good evidence that there has been no falling off in its usefulness and no disposition to interfere with its healthy and regular growth. During the year Mr. W. M. Tattersall has succeeded Dr. Hoyle as keeper of the museum. The number of additions to the collections has been large in every department, and the library has been considerably strengthened during the year.

THE first issue of the *Naturalist*, the journal of the Natal Scientific Society, has been received. We understand that this scientific periodical is the only one of its kind published in South Africa. It is edited by Mr. R. Denley James, and, in addition to containing the society's transactions and proceedings, includes several articles. Among the latter may be mentioned notes on the life-history of the Pseudacræa by Mr. A. D. Millar, and a short note on the Ixodidæ by the editor. The syllabus of work which the society hopes to accomplish during the present session shows that most branches of science are to receive attention, and that already the society has received gratifying support.

THE decay of building stones was discussed by Dr. Tempest Anderson at the recent Museum Conference at York, and his address is published in the October number of the *Museums Journal*. After showing that stone-decay is not due to wind action, the opinion is expressed that "it is not a surface action at all, but, I believe, a decay or rot affecting the substance of the stone, and, like other decays and rots, is in every probability caused by the action of some low organism, like the moulds and fungi which rot wood, canvas, and other vegetable materials. About two years ago, to test this view and endeavour to find a cure, as all efforts based on the abrasion or chemical theories had failed, I had affected stones treated with various germicides, and the stones which have since best resisted the decay were those treated with sulphate of copper (5 per cent. solution), bichloride of mercury, and creosote."

THE specimens of beaked whales (Ziphiidæ) in the collection of the United States National Museum form the subject of a profusely illustrated monograph, by Mr. F. W. True, published by the Smithsonian Institute as Bulletin No. 73. On account of the rarity of these cetaceans—exclusive, of course, of the bottle-nosed whale—the memoir

has an exceptional value to the students of the group, more particularly since the U.S. National Museum possesses, so far as the author could ascertain, about one-fourth of the whole available material. Of the genera Mesoplodon, Ziphius, and Berardius, Mr. True could find records of only about one hundred specimens in collections, of which more than half belong to the first genus, Berardius being known only by about fourteen examples. The most important addition to our knowledge of the group in recent years was the discovery of representatives of all three genera at Bering Island by Dr. Stejneger, two of these being regarded as distinct species, one of which was named in 1883 and the other in 1885. About six years ago it was ascertained that the range of the Bering Sea forms extends to the eastern North Pacific. After a descriptive catalogue of the specimens in the Washington Museum, with notices of some examples in other American collections, the author concludes his memoir with a list of the recognisable existing species of the group. Inclusive of the two representatives of Hyperoödon, this list embraces thirteen species.

THE November number of the *Quarterly Journal of Microscopical Science* (vol. lv., part iv.) contains a very interesting paper by Miss Muriel Robertson and Prof. E. A. Minchin on the division of the collar-cells of the calcareous sponge *Clathrina coriacea*. It appears that these cells multiply by longitudinal fission, the division of the nucleus being accompanied by a typical mitosis. The chief interest attaches to the behaviour of the "blepharoplast" in this process. In the resting cell this organ appears as a "basal granule" in connection with the flagellum; in mitosis it behaves as a typical "centrosome," dividing into two parts, which cave to lie at opposite poles of the nuclear spindle. Each of these daughter centrosomes becomes the blepharoplast of one of the daughter cells, and a new flagellum grows out from it. Around each new flagellum a new collar develops, the old collar and flagellum of the mother cell completely disappearing. The authors discuss the bearing of these facts upon the vexed question of the interpretation of the "kinetonucleus" in trypanosomes, and conclude that the latter is a true nuclear body, and not a blepharoplast or centrosome.

THE destruction of agricultural plant pests by chemical means is reviewed by Mr. H. C. Long in *Knowledge* (November). The practice is based on direct experiment, as plants differ considerably in their resistance to chemical solutions; thus charlock and dandelions are readily attacked by a copper sulphate solution, while *Cnicus arvensis* and clover are much more resistant. According to Bolley, shepherd's purse, *Camellina sativa*, chickweed, corn-cockle, bindweed, and plantain are all amenable to chemical treatment, whereas sow-thistle, *Bromus secalinus*, wild oats, and couch grass cannot be effectively controlled. The author directs attention to the desirability of carrying out systematised experiments in different parts of the country.

AN account of the Arnold Arboretum, well known by name to British botanists, is contributed by Mr. W. J. Bean to the *Kew Bulletin* (No. 8). Situated in a suburb of Boston, U.S.A., and extending over 200 acres, it is noted for the large collection of trees and shrubs in which north-east American and north Asiatic species predominate. A marked feature in the arboretum is the ground cover of shrubs in place of grass around the trees; various species of Vaccinium, Aster, Rubus, and other native shrubs are grown in this way. Mr. Bean pays a warm tribute to the energetic director, Prof. C. S. Sargent, for the excellent work that is being carried on; one of his greatest tasks has been the elucidation of North American species of Cratægus, of which specimens from type plants occupy 15 acres. A monumental work was provided by the "Silva of North America," in fourteen volumes, and another massive publication that will shortly appear is a bibliography of trees and shrubs of the world. Incidentally, the *Bulletin* contains evidence of cordial cooperation between Prof. Sargent and Kew in the publication of a list of new species of Impatiens from China, forwarded to Sir Joseph Hooker by Prof. Sargent for description.

THE report of the chief inspector of mines of the native State of Mysore for the year 1908 has just been issued, and affords satisfactory evidence that mining operations are being conducted here with energy and skill as well as with due attention to the safety of those engaged in the work. A small amount of manganese and chrome ore is being raised, but the principal mining operations are, as heretofore, confined to the Kolar goldfield. The report shows that there were ten companies at work, of which seven were producing gold, the value of the bullion produced being just over 2,000,000*l.* sterling, or almost exactly the same as in the previous year. The quartz raised contains gold to the value of just about 3*l.* per ton, the working costs amounting to about one-half of this figure. Elaborate tables are attached to the report, those relating to occidents being especially interesting. The accident death-rate is given as 4·70 per 1000 persons employed below ground, a figure which, though necessarily varying a good deal from year to year, shows upon the whole a downward tendency. A comparison with the similar figure for the Transvaal goldfields is decidedly in favour of the Kolar field, although in the Transvaal the accident death-rate per 100,000 tons of quartz treated is less than in Mysore, due to the greater efficiency of the Kaffir as compared to the Indian miner. In the Mysore there are about 4000 persons employed for each ton of quartz crushed, as against about 1000 in the Transvaal. A good deal of space in the report is devoted to a discussion of the "air-blasts and quakes," or violent bumps of ground, due apparently to the sudden relief of the strains in the ground as mining proceeds. These bumps have caused a good many serious accidents, and up to the present no means of preventing them has yet been suggested. It is to be hoped that a further study of this intricate question may lead at any rate to a determination of the conditions under which they are likely to occur, this being the first step towards taking measures to minimise the dangers resulting from them.

ON assuming his extraordinary professorship at the National University at Utrecht, Dr. E. van Everdingen delivered an interesting address, on October 17, upon "The Third Dimension in Meteorology." The establishment of a separate chair for meteorology was, he thought, an admission that it was now considered worthy of taking a place among the older sciences. If we inquired in what direction it had developed in the last twenty years, the answer undoubtedly was, in the third dimension: height. After glancing at the history of meteorology from the earliest times, he referred to the great importance of Buys Ballot's work in investigating simultaneous weather conditions and in formulating his law of the relation of wind to air-pressure, which is still the corner-stone of practical meteorology, and had infused new life into the subject. He discussed in considerable detail the various methods employed, and the valuable results obtained in the investigation of the upper air by (1) manned balloons; (2) kites; (3) captive balloons; (4) registering balloons (with instru-

ments); and (5) pilot balloons (without instruments). The use of Assmann's aspirating-psychrometer in manned balloons, and his employment of rubber both in registering and pilot balloons in lieu of paper, have proved of the greatest value. The author shows that much new light has been thrown upon questions relating to the general circulation of the atmosphere by the important discovery of the inversions of temperature at great heights and the existence of the isothermal layer, not only in our latitudes, but also in polar and tropical regions. At moderate heights these inversions play an active part in thunderstorm phenomena.

THE October number of *Himmel und Erde* contains an account of a popular lecture on the present position of wireless telegraphy, delivered six months ago by Dr. Karl Strecker, of the Imperial Post Office, Berlin. The account is well illustrated by diagrams, and is one of the best popular introductions to the subject we have seen. The author commences with the up-and-down oscillations of a weight supported by a spring, and the property such an arrangement has of setting in oscillation a similar arrangement suspended from the same beam as the first. By simple steps he passes to the oscillations of electricity in two conducting rods separated by a spark-gap, and to the way in which a duplicate apparatus at a distance will pick up the oscillations. The defects of the earlier apparatus are explained, and it is shown how in succession the means of detection of the oscillations and the means of producing them have been improved by the introduction of the coherer and by the utilisation of the oscillations produced by a cooled electric arc. Even the problem of privacy is not overlooked, and it seems the author considers rapid and prearranged changes of frequency of the oscillations as the future solution of the difficulty.

THE discovery by Messrs. Cotton and Mouton three years ago that a liquid may be rendered double refracting by the action of a magnetic field redirected attention to the Kerr effect, and as a result we now have theories which attempt to explain both effects. Prof. Voigt in his "Magneto- und Elektro-Optik" traces them to a direct effect of the electric or magnetic field on the electromagnetic oscillations which constitute light, while Prof. L. Natanson, in the June number of the Bulletin of the Academy of Sciences of Cracow, treats them as due to the directive action of the field on the electrons oscillating within the molecules. In the September number of *Le Radium* Prof. Langevin extends his theory of magnetisation so as to cover the two effects. According to him, the molecules of the liquid have axes along which the polarisation is an electric, and the magnetic moment in a magnetic field have values which differ from those in directions at right angles. Æolopropy of the molecule once secured, either on Prof. Natanson's or Prof. Langevin's theory, the investigation of the effects proceed along lines similar to those of Dr. T. H. Havelock's Royal Society paper of 1907, and leads to results in agreement with observation—that the amount of the double refraction is proportional to the square of the field, and the dispersion is expressed by Cauchy's formula.

AN interesting paper on the development of road locomotion in recent years was read by Mr. L. A. Legros at the Institution of Mechanical Engineers on Friday, November 18. It is difficult to realise the enormous increase in the use of the cycle both for pleasure and business purposes. It is estimated that about one person in every fifteen of the entire population of the United Kingdom is a cyclist. Post Office cycles cover a distance of 10,000 miles per annum per machine. The total number in use for postal purposes is 11,400. It is noteworthy that in the total mileage which has been run since the service was instituted, viz. about 600,000,000 miles, no fatal accident has occurred by the failure of any portion of a bicycle. The author estimates that the various public service horsed vehicles in London will become extinct as follows:—the horse-tramcar at the end of 1912; the horse-omnibus at the end of 1913; the hansom cab at the end of 1913; the four-wheel horse-cab before the end of 1921. The paper contains many useful suggestions regarding the management of traffic in London streets.

AN illustrated article on the removing of the wreck of the Quebec Bridge appears in the *Engineer* for November 18. The contract for clearing the site was awarded last December to Messrs. Charles Koenig and Co., of Quebec, and about half the quantity, viz. 5000 tons, has now been removed. A large amount of cutting has had to be done, and the choice of either dynamite or oxyacetylene for cutting a member is governed very largely by local conditions. Where the latter method has been used to greatest advantage has been in cutting up the heavy chords and posts into pieces that could be handled by the derricks, which have a capacity of not more than 10 tons. One web, 4 feet 6 inches deep, with a section of 190 square inches, was cut in 20½ minutes with a consumption of 112 cubic feet of gas. In cutting eyebars it was found that with a stream of pure oxygen gas one square inch of metal could be cut, on an average, in 5⅝ seconds, with a consumption of 0·4 cubic foot of gas, at a cost of 1·2 cents for the oxygen gas. Since the beginning of operations some 50,000 cubic feet of gas have been consumed, or an average of 10 cubic feet per ton of material removed.

MESSRS. SCHOTT AND GEN, of Jena, have sent us a copy of a well-illustrated catalogue of the new Jena glass laboratory requisites they are now in a position to supply. Extracts are published in the catalogue from a report from the Imperial Physico-Technical Institute, Charlottenburg, made after subjecting the new ware to various tests, and they indicate that these requisites, in comparison with older Jena glasses, have an increased power of resistance to sudden changes of temperature combined with a reduction of the amount of alkali given off into aqueous fluids.

OUR ASTRONOMICAL COLUMN.

THE TOTAL ECLIPSE OF THE MOON, NOVEMBER 16.—Not for many years have the conditions for observing a total eclipse of the moon been so generally favourable as they were on November 16. Reports from all over the country show how generally they were taken advantage of and appreciated, although, of course, no details of special scientific interest are yet published. Several meteors were observed before and during the eclipse, Mr. E. A. Martin having observed one at 6h. 55m. p.m. from South Norwood. Its path was from north-west to south-east, its colour reddish-yellow, and it was especially noticeable by reason of its extremely leisurely movement. Two faint meteors travelling in the same direction were seen from Gunnersbury during the eclipse. Madam de Robeck, writing from Naas, Ireland, states that the eclipse was a beautiful spectacle, and that she saw three meteors. One of these was a fine specimen, which travelled in a south-westerly direction from an apparent radiant just below the eclipsed moon. The penumbral shadow was barely discernible until after 10 p.m., when the relative darkening of the south-east limb could be detected. A slight flattening of the limb appeared to take place some minutes before the actual shadow could be seen on the disc, and throughout the eclipse the various prominent

lunar features were readily distinguishable through the deep copper-coloured shade. During totality the relative brightness of the limb was also noticeable, a thin ring appearing to encircle the darkened disc. The beauty of the phenomenon was considerably increased by the apparition of previously unseen stars, notably the Pleiades, when the extreme brightness of the moon was reduced. It is gratifying to notice that the new 8-inch equatorial of the Birmingham University Observatory was employed by Mr. Fournier in taking some fifteen photographs of the eclipsed moon during the various phases of the eclipse; exposures of from one to thirty seconds were given.

CERULLI'S COMET, 1910*e*.—Numerous observations of the comet discovered by Dr. Cerulli on November 9 appear in the supplement to No. 4454 of the *Astronomische Nachrichten*. As seen by Prof. Hartwig at Bamberg on November 11 the comet was of the tenth magnitude, round, 2′ diameter, and had a faint condensation.

From observations made on November 9, 10, and 11, Dr. Ebell has calculated a set of elements and an ephemeris, and from the former it appears that perihelion passage took place on September 15; at present the comet is about 95 million miles from the earth, and is receding at the rate of 720,000 miles daily. Apparently it is travelling nearly due south through the southern limits of Taurus, as shown by the following extract from the ephemeris:—

Ephemeris 12h. M.T. Berlin.

1910	α (true) h. m.	δ (true) ° ′	1910	α (true) h. m.	δ (true) ° ′
Nov. 23	3 37·3	+5 37·4	Dec. 1	3 36·9	+4 24·5
,, 27	3 37·0	+4 58·0	,, 5	3 36·9	+3 57·3

SELENIUM PHOTOMETRY OF STARS.—A paper of more than usual interest, in which the author discusses at length his measures of Algol, made with his selenium photometer, is contributed by Dr. Joel Stebbins to No. 3, vol. xxxii., of the *Astrophysical Journal*. The photometer was attached to a 12-inch refractor, and was kept at a uniform temperature of 0° C. or lower; the galvanometer current was kept working continuously, and between each ten seconds' exposure to a star the cell was rested for about a minute in order to recover; α and δ Persei were used as comparisons.

Under these necessary conditions very careful observations were made, and Dr. Stebbins considers that the results show the method to be capable of greater accuracy than is attained in visual observations. Among many interesting results accruing from the work, the following call for special mention. The companion gives more light than the sun, and is much brighter on the side turned towards Algol. A secondary minimum, some thirty-five hours after the principal minimum, was detected, the variation being only 0·06 magnitude. The discussion indicates that the radius of the companion is 1·14 that of Algol, while the limiting densities are 0·12 and 0·18 of the sun's density respectively. The total period comes out as 68·816h., and the duration of the eclipse as 9·8h. The greater luminosity of the one side of the companion, which appears to rotate and revolve in the same time, may be accounted for by supposing that it is intensely heated by radiations from the primary; this is in general agreement with Dr. Nordmann's suggestion that the temperature of Algol, as measured by his method, is great enough to raise the surface of the satellite to incandescence. Taking the parallax of the system as +0·07″ and the sun's magnitude as −26·6, the total light of Algol is 26; the total light of the faint hemisphere of companion is 1·7, and of the bright side 3·0; this would give stellar magnitudes of 2·2, 5·2, and 4·6 respectively. But if Kapteyn's adopted value for the parallax, +0·029″, and his magnitude of the sun, −26·1, be employed, these brightnesses become, respectively, 240, 16, and 28 times that of the sun.

Many other points, such as the density, magnitude, and form of the system of Algol, are also discussed in Dr. Stebbins's paper.

THE SECULAR ACCELERATION OF THE MOON'S MEAN MOTION.—In No. 4454 of the *Astronomische Nachrichten* Dr. Robert Bryant advances the tentative suggestion that the secular acceleration of the moon's mean motion may be due to the accretion of "dust" from interplanetary space by the moon and the earth. He finds that a deposit of 2 mm. of "dust" per century on the lunar surface would, if the density of the "dust" were equal to the mean density of the moon, account for about 6″ per century in the moon's longitude; a deposit on the earth would also be reflected in the longitude of the satellite.

It is also suggested that uniform distribution of the "dust" is improbable, hence irregularities would accrue. If the earth does collect sufficient "dust" in this way, its rotation period would be affected irregularly, and astronomy of precision would obviously be confronted by a serious difficulty.

PHOTOGRAPHIC MAGNITUDES OF SEVENTY-ONE PLEIADES STARS.—From the extra-focal images impressed upon thirteen plates taken early in March last, Herr Adolf Hnatek has determined the photographic magnitudes of seventy-one stars in the Pleiades group, and now publishes the results in No. 4449 of the *Astronomische Nachrichten*. The photographs were taken with the 14-inch photographic refractor of the Vienna Observatory, 10 mm. inside the focus, and the author publishes an interesting discussion of the results and the method whereby they were derived; an especially interesting point discussed is the effect on the apparent magnitude caused by the distance from the centre of the plate.

ELEMENTS AND NUMBERS OF RECENTLY DISCOVERED MINOR PLANETS.—Prof. Neugebauer publishes, in No. 4454 of the *Astronomische Nachrichten* the elements and permanent numbers of eighteen minor planets discovered during 1909; the last number allotted is 691, so that the total number of discoveries must, by now, be well above 700.

A NEW THEORY OF THE DESCENT OF MAN.[1]

THE first of the memoirs referred to below relates to the discovery of a new Palæolithic skeleton, and contains a careful report by Hauser on the excavation, along with a critical description of the skeleton and a comparison of the same with other known types, more especially with the Neanderthal man, from the pen of Prof. Klaatsch.

The conclusion arrived at is that the Neanderthal man and the Aurignac man represent two entirely different types of mankind.

According to Hauser's report, the skeleton of the Aurignac man was found early in 1909, at the Palæolithic site of Combe-Capelle, not far from Montferrand (Perigord), at a depth of 1·54 m. in a typical Aurignacian stratum, as was clearly proved by the artefacts found with the skeleton. The skeleton lay under a rock shelter, and was almost complete, the only imperfections being due to the displacement of certain parts by overturned masses of rock. As to the position of the body, the knees were strongly bent and drawn towards the head; the feet were also drawn together in a way which suggested a squatting position. After the whole skeleton had been removed, it was evident that the ground had been artificially prepared for the burial of the dead. There were found in the grave, typical Aurignacian artefacts of beautiful form, and perforated specimens of *Nassa reticulata*, a small marine snail, these articles being evidently intended for grave finery. The mode of burial showed the high state of culture of the Aurignac man.

A glance at diagrams of the Neanderthal and Aurignac skulls is sufficient to show the smaller breadth and more considerable height of the latter as compared with the former. Klaatsch directs attention to the stronger arching of the forehead of the Aurignac man, the greater bregma angle and calottic height, both according to Schwalbe's system as well as his own; the calottic height measurement of the Neanderthal skull is 40·4, while that

[1] H. Klaatsch und O. Hauser, "Homo aurignacensis Hauseri, ein palæolithischer Skelettfund aus dem unteren Aurignacien der Station Combe-capelle bei Montferrand (Périgord)." *Praehistorische Zeitschrift*, 1910, Heft 3–4, pp. 273–338, Tafel xxv–xxxv und drei Beilagen. (Berlin, 1910.)
H. Klaatsch, "Die Aurignac-Rasse und ihre Stellung im Stammbaum der Menschheit." *Zeitschrift für Ethnologie*, Jahrgang, 1910, Heft 3–4, pp. 513–577, Mit Tafel ii–iv und 46 Figuren im Text. (Berlin, 1910.)

of the Aurignac skull is 54·45. The excessive prominence of the Neanderthal skull in the frontal region is absent in the Aurignac skull, in which there is no development of an undivided torus supraorbitalis. Corresponding differences between the Aurignac and the Neanderthal skulls are found in the posterior region. The marked separation of the torus occipitalis transversus into a right and left half, which characterises the Neanderthal skull, is completely wanting in the Aurignac skull, of which the posterior region exhibits a quite remarkable conical extension. The place corresponding to the transverse inion prominence of the Neanderthal type is occupied by a sharp transverse ridge. The region of the planum nuchale lying below this shows a slightly hollowed surface.

In adults of primitive types of men, the sinus transversus does not coincide with the linea nuchae superior, as in modern Europeans. This condition is found both in the Neanderthal and in the Aurignac skull; it is, however, not to be regarded as evidence of an affinity between these two races, but merely as a character preserved from a common primitive condition.

In the temporal bone there is, in the case of the Aurignac man, a considerable protuberance of the conical-shaped mastoid, which contrasts strongly with the broad, low mastoid of the Neanderthal skull.

The cavity for the origin of the posterior belly of the digastric muscle is, in the case of the Neanderthal skulls (Spy, Moustier), wide and flat, and makes its appearance behind the mastoid. In the Aurignac skull the digastric groove is narrow and slight.

The tympanicum is, in the Aurignac skull, of remarkable delicacy, but is of considerable thickness both in the Moustier and Spy remains (Neanderthal type).

The formation of the facial bones also shows quite fundamental differences in the two types.

A fuller discussion of the anatomical details of the skeletons is outside the scope of a short article, and for this the reader is referred, especially as regards the anatomy of the extremities, to the original memoir.

The second memoir lays claim to the widest interest, especially as regards its conclusions about the general biology of man, and promises to open up new paths for the study of the morphological details of the skeletons of the primates. A series of special morphological results leads to the discovery of a parallel between the differences of the Aurignac and Neanderthal men, and the differences of the gorilla and orang-utan.

These considerations demand especially a rigid separation of accidental convergence phenomena from such characteristics of morphological details which must have been conserved by heredity alone, since they have no demonstrable connection with functional adaptations.

The external resemblance of the orang, of the gorilla, and of man in the sagittal and occipital crests is a convergence phenomenon. It is to be regarded as such because it is essentially a superficial resemblance, and exhibits great differences in its mode of origin. For example, the temporal muscles have left their imprint on quite different parts of the sides of the skull, from which it is to be inferred that before the beginning of this process the two skull forms were undoubtedly different, the orang having a higher forehead and a smaller supraorbital prominence than the gorilla.

On the other hand, Klaatsch finds in the ratio of the longitudinal and transverse diameters of the head of the humerus a morphological character which is important for the determination of affinities. We can here select only a few of the numerous details which serve as vouchers for the affinity between the orang and the Aurignac man on one hand, and between the gorilla and the Neanderthal man on the other.

The spina tuberculi majoris and the sulcus intertubercularis of the humerus in the case of Aurignac man and the orang run almost straight down, while in the case of Neanderthal man and the gorilla they both describe a medial convex curve. The peculiar rough insertion of the pectoral muscle is common to the Neanderthal and the gorilla. On the tibia, the relief of the posterior surface of the malleolus—the grooves for the flexor muscles—is deeper in the case of the orang than in the case of the gorilla; the same distinction holds between the Aurignac and the Neanderthal. On the femur, the trochanter minor in the case of the Neanderthal and gorilla is further down the shaft, and projects more inwards, while in the case of the Aurignac and the orang it projects backwards. The Aurignac-orang type exhibits also in the distal part a distinctly projecting, obliquely descending, crista intertrochanterica; in the Neanderthal-gorilla type there occurs that weakening of the ridge above the trochanter minor to which Klaatsch has already directed attention in the Neanderthal femur.

The shaft of the Aurignac femur is remarkable for its extraordinary straightness, and we find the same character in general with the orang. In contradistinction to this is the forward convex bend of the Neanderthal and gorilla femurs.

Klaatsch supports his theory by many more morphological details. Of special interest are the congruence phenomena which are shown by the curve diagrams of the tibia to exist between Aurignac and the orang and the gorilla and Neanderthal, as well as the similarity of the shaft proportions of the tibia of Spy and the gorilla.

All these details show that there exists an affinity in important morphological details between the Aurignac man and the orang-utan and between the Neanderthal man and the gorilla, and that this does not rest only on the general impression produced by the graceful and slender appearance of many of the parts of the orang and Aurignac as contrasted with the rough and thick-set build of the gorilla and Neanderthal.

These considerations unfold to us promising views of the coming problems of anthropology, and throw new light on our present conceptions of the phylogeny of the human race. From a study of the osteological details we are driven to the conclusion that at a very early epoch there branched off from the primeval common mass of our forerunners—Propithecanthropi, as Klaatsch calls them—a great western stream and a great eastern stream. Inside each of these groups new segregations occurred which led partly to the formation of races of anthropoid apes and partly to the formation of races of men.

The anthropoid apes are to be regarded as representing the unsuccessful attempts and dashes forward towards the goal of the definite creation of the human race—submerged branches of the primeval humanity which, in adapting themselves to special conditions of life, were

compelled in the struggle for existence to sacrifice important parts of their organisation, while a more favoured collateral branch, in quiet progressive evolution, developed into a human race.

By a new kind of diagram Klaatsch endeavours to elucidate the distribution of the human races and the anthropoid apes. The femur of Pithecanthropus fixes its position in the neighbourhood of the eastern group. The chimpanse is in many respects further removed from the gorilla than from the Neanderthal man. The African races exhibit some affinities with the Neanderthal type. As to the eastern people, the similarities between the skulls of young orangs and the skulls of Javanese, which impressed certain authors, require further investigation.

With the help of his new theory, Klaatsch promises us a new interpretation of single pieces of the diluvial find of Krapina, some of these apparently belonging to the Aurignac type and others the Neanderthal type.

Of all earlier finds, the skeletal remains from Galley Hill, Kent, have the greatest affinity with the Aurignac man. Less certain are the affinities of the skull from Engis. A new comparison of the other diluvial and early prehistoric finds from the point of view of the new theory appears to be highly desirable.

Richard N. Wegner.

MINERAL PRODUCTION OF INDIA.[1]

THIS quinquennial review of the mineral output of India is probably the last official publication of Sir Thomas Holland in his capacity as Director of the Geological Survey of India, and it is especially appropriate that this should be so, seeing not only that he originated this most useful form of publishing the records of Indian mineral production, but that he has been the first of all the directors of the Survey to recognise that the chief duty of this survey is to assist and encourage the development of the mineral resources of the country. It is an undoubted fact, to which the present report bears eloquent witness, that the mineral production of India increased during Sir Thomas Holland's directorship at a rate with which no previous similar period of Indian history can show any comparison.

A glance at the records before us shows that the last five years have continued the energetic development of the mineral resources of the peninsula; as pointed out by the authors, it is practically impossible to set up any unexceptional standard of valuation, so that accurate comparisons cannot well be looked for; yet, even allowing for this fact, an increase in the estimated value of the output from 3,455,565*l.* in 1898 to 5,047,201*l.* in 1903, and from this figure, again, to 7,880,832*l.* in 1908, is a clear proof of a steady rise in the exploitation of these important resources of our Indian Empire. Of the total value thus assigned to the production, about two-thirds are made up of two items, gold and coal, the latter being now by far the more important; in 1903 the value of the gold was nearly twice that assigned to the coal, whereas in 1908 the latter figure was about 50 per cent. greater than the former. The gold output has, in fact, remained just about stationary during the period under review, the great bulk of it coming, as hitherto, from the Mysore mines.

The important increase in the coal production is perhaps one of the most satisfactory features indicated in this report; from $1\frac{1}{2}$ million tons in 1884, the output rose steadily to $8\frac{1}{2}$ millions in 1905, and then more rapidly to nearly 13 millions in 1908. About 90 per cent. of the entire output comes from Bengal, and about 50 per cent. from a single coalfield, namely, Jherria, which is now the leading coalfield, having gone ahead of Ranigunj since 1906. A very interesting statement is here published concerning the geological age of these Bengal coalfields; they occur in the Damuda series of the Gondwana system, which has always been looked upon as of Mesozoic age, the Lower Gondwanas being classed as probably of Triassic and the Upper Gondwanas as probably of Jurassic age, thus making the coal-bearing formations much younger than those of Europe. On palæontological evidence, it is now possible to assert that the Lower Gondwanas are Palæozoic, and "certainly not younger than the Upper Carboniferous. Thus the Indian Coal-measures are not much younger than, and may even be of the same age as, those of Europe."

The only other point of especial importance is, in contradistinction to the first one, a purely economic one, namely, the fact that within the period under review the first battery of bye-product coke ovens has been erected on an Indian coalfield, namely, at Giridih.

During the five years to which this report refers the number of persons engaged in coal-mining has increased from 92,740 to 129,173, the numbers of those at work underground being respectively 64,969 and 83,164. The output has thus risen more rapidly than the number of persons employed, showing an increase in efficiency in the workers. The output per person employed has risen from 88·6 tons in 1904 to 98·8 tons in 1908, and per worker underground from 126·4 tons in 1904 to 153·5 tons in 1908. The efficiency of the Indian worker is thus approximately one-third of that of the worker in the United Kingdom; as is correctly pointed out in the report, this figure does not properly represent the ratio of labour efficiency, because in India a great deal of work is done by hand which in the United Kingdom is done by machinery, simply on account of the cheapness and abundance of labour in the peninsula. The death-rate from accidents has shown a marked tendency to increase during the last five years, but it is not possible to say whether this fact is due to the increasing depth of the mines or to accidental circumstances; its average over the five years 1904–8 is 0·98 per 1000 persons employed, or 10·2 per 1,000,000 tons of coal raised; the corresponding figures for the United Kingdom in 1906 were 1·29 and 4·37 respectively.

Another mineral that now bulks largely in the mineral production of India is manganese ore, the output of which shows a very marked increase, namely, from 150,190 tons in 1904 to 674,315 tons in 1908. The output in this latter year was about 228,000 tons less than that of the previous year, the falling off being due to market conditions, and in no wise indicating that the productive capacity has reached its zenith and is commencing to decline; on the contrary, it may be confidently anticipated that the general expansion above indicated will continue. The interesting economic question is raised whether it would not be preferable to smelt a considerable proportion of this ore on the spot, and thus export ferro-manganese instead of manganese ore; seeing that about one-fourth of the selling price of the ore represents the cost of freight, it is obvious that the possibility exists of effecting a very considerable saving, and the question should well merit investigation at the hands of the producers of manganese ore.

India is of great importance as a producer of mica, the Indian output being well over one-half of the world's total production. Here again a great increase is to be noted, namely, from 22,164 cwt. in 1904 to 53,543 cwt. in 1908.

The production of petroleum, still almost entirely from Burma, has also shown an increase, namely, from 118,491,382 gallons in 1904 to 176,646,320 gallons in 1908; even this latter figure is insufficient to supply the needs of the country, which imported about 70 million gallons in 1908.

It may be fairly said that the above comprise the mineral products of most importance; there are, of course, numerous others, and in most cases these show a marked increase in output. It is gratifying to find that the exertions of a scientific institution like the Geological Survey are having such a beneficial effect upon the economic development of the peninsula; and whilst congratulating Sir Thomas Holland upon the success in this direction that has attended his tenure of the directorship of the Geological Survey, we may express the hope that this expansion of the material interests of the country will continue to be the first care of his successors, with the same gratifying results.

SCIENCE AND ENGINEERING.

AT a meeting of the Junior Institution of Engineers on November 15, Sir J. J. Thomson, F.R.S., president of the association, delivered an address on the relations between pure science and engineering. The distinction between them, he said, is one of aim, not of method. The methods employed by the physicist and the qualities of mind called into play in his investigations are to a large extent the same as those used by the engineer in the higher branches of engineering. It is not the business of the physicist in his researches to concern himself at all with utility. Almost every advance in pure physics has been turned to account by the engineer, the manufacturer, or the doctor. But nothing would be more disastrous to the progress of engineering than that the workers in pure science should hamper themselves by considerations as to the utility of their work, or confine their attention to points which have an obvious practical application.

The province of engineering is to survey the facts known to science, and to select those which seem to have in them the possibilities of industrial application, and then to study and develop them from this point of view. This can often best be done in laboratories attached to works engaged in active trade. The success of works' laboratories in Germany and the United States, and to a growing extent in this country, is one of the most striking features in modern industrial development. A closer connection with pure science would be of the greatest service to engineering and commerce in this country, and though strides have been made in this direction in recent years, Sir J. J. Thomson pointed out we are still behind Germany in the importance we attach to pure science and in the eagerness with which new discoveries are applied to industrial purposes. As an instance, to judge from the number of "Thermos flasks" met with, the manufacture of these flasks must constitute a large and profitable business. It is said, however, that none of these flasks is made in England. Yet the Thermos flask is an English invention, being nothing but what is known to physicists as the "Dewar vessel," which was invented by Sir James Dewar for the purpose of storing liquid air without evaporation, and was described by him some years ago. Although the discovery was made and first published in England, no English manufacturer took it up, but left it to foreign rivals to make it the basis of an important trade.

It is, he continued, the object of applied science to keep theory and practice at the same level. Theory and practice do better work when they are driven abreast rather than in tandem. The more intimate the relation between the workers in pure science and those engaged in the application of science, the greater will be the opportunities of deepening the faith in science of the practical man. Faith in the results of pure science is more robust in Germany and the United States than in this country; here we cultivate more exclusively things which ripen quickly and yield an immediate return upon the capital invested, and are inclined to turn aside from projects which, though more profitable in the long run, will, so to speak, take a long time before they come into bearing.

ZOOLOGY IN THE INDIAN EMPIRE.

TO the September number of *Spolia Zeylanica* Prof. Punnett contributes an important paper, illustrated by two double coloured plates, on mimicry in Ceylon butterflies, with a suggestion as to the nature of polymorphism. After giving a list of the hitherto recorded instances, which are relatively numerous in comparison with the extent of the fauna, the author points out that this mimicry is far less striking among the living insects than in museum specimens. Not only is this difference apparent on the under surface of the wings when the insects are at rest, but it is still more noticeable in the mode of flight, so that with very little experience the eye learns to distinguish between the mimic and the mimicked. In the well-known case of *Papilio polyotes*, with its three phases of females, one of which closely resembles the male of the same species, while the second mimics the male of *P. aristolochiae*, and the third that of *P. hector*—both the two latter being inedible, while the first is edible—the author observes "that though model and mimic may be readily distinguished at rest, whether with wings expanded or closed, yet the resemblance between them may be sufficient to deceive such enemies as attack them when flying. Such, however, is certainly not the case. The mode of flight of *P. polyotes* is similar for all three forms, and is totally distinct from that of *P. hector* and *P. aristolochiae*.

After referring to the distribution of the three species and the relative numbers of the males and females of the different forms in various localities, the author states that the facts "are far from lending support to the view that the polymorphic females of *P. polyotes* have owed their origin to natural selection in the way that the upholders of the theory of mimicry would have us believe."

For Prof. Punnett's suggestion as to the origin of polymorphic females our readers may be referred to the original paper, as it is too long to quote, but it may be mentioned that Mendelism plays a part in the explanation. Mimicry in other species, together with the natural enemies of butterflies in Ceylon, is likewise discussed.

In the same issue Mr. George Duncker, after mentioning that although the group is common in the fresh waters of India and East Africa, none has been hitherto recorded from those of Ceylon, states that during the summer of 1909 he succeeded in obtaining examples of four species—one of which is new—of pipe-fishes of the family Syngnathidæ from the rivers of that island.

With the exception of one devoted to a South African frog allied to *Rana corrugata* of Ceylon, the articles in part iii. of the fifth volume of the Records of the Indian Museum deal with invertebrates of various groups. Among these papers is one by Dr. Annandale on a new genus of psychodid Diptera from the Himalaya and Travancore, based on a minute species from Darjiling, described earlier in the present year by Dr. Annandale as *Diplonema superstes*; this now becomes *Brunettia superstes*, while the new Travancore species is to be known as *B. travancorica*. In a second paper the same writer discusses the Indian scalpelloid barnacles of the subgenus Smilium, while in a third Mr. S. Kemp describes three new Indian species of the marine decapod genus Gennadas. Most interesting of all is an article by Mr. C. A. Pavia on the larvæ of a common Calcutta mosquito, known as *Toxorhynchites immisericors*. It was suspected that these larvæ feed on the larvæ of another mosquito, *Stegomyia fasciata*, frequently found in water contained in earthen vessels, and experiment has proved the surmise to be true. The larvæ of *T. immisericors* feed, in fact, greedily on those of Stegomyia, "and as *S. fasciata*, the yellow-fever mosquito, is very common in earthern pots round Calcutta, one is justified in assuming that *T. immisericors* plays an important part in its destruction, in a manner which would be of great moment in the event of yellow fever being introduced into the country."

R. L.

THE ARRIVAL OF MAN IN BRITAIN.[1]

THE address dealt with the antiquity of man as revealed in the geological record, and with the conditions under which Palæolithic man arrived in Britain. In the Tertiary period the higher (Eutherian) Mammalia appear, *en pleine évolution*, and afford the means of classifying it into the following well-marked divisions:—(1) The Eocene, in which living families and orders appear and there are no living genera. (2) The Miocene, in which there are living genera and no living species. (3) The Pliocene, in which the extinct species are preponderant and living species appear. (4) The Pleistocene, in which the living species are preponderant, and the extinct are few in number; Palæolithic man appears. (5) The Prehistoric, in which there are no extinct species of land Mammalia, and man is in the stages of culture marked by the use of Neolithic, bronze, and prehistoric iron implements. (6) The Historic period, in which the events are recorded in history.

In this classification the evolution of the Tertiary Mammalia takes the shape of a genealogical tree with

[1] Abstract of the Huxley Memorial Lecture delivered before the Royal Anthropological Institute on November 22 by Prof. W. Boyd Dawkins, F.R.S.

its trunk hidden in the Secondary period and its branches and twigs passing upwards through all the stages—a tree of life with the living forms as its fruit, the extinct species filling up the intervals between the living forms, and approximating to them in proportion as they approach nearer to the present day. In our search for the first traces of man on the earth, it is obvious that we cannot expect to find the most highly organised of the Mammalia in any portion of the geological record where there are no other living mammalian species, or, in other words, in the two earlier stages of the Tertiary period—in the Eocene, where there are no living Eutherian genera, and in the Miocene, where there are no living species. We may search for him in the Pliocene stage, when the living species come in, with some small chance of success, but our main efforts must be directed to the Pleistocene stage, when the living Eutherian forms were dominant and the face of nature as a whole was almost as it is to-day. If the doctrine of evolution be true there was no place for man in nature in the Eocene and Miocene stages, and if he had then been on the earth it is incredible that he should not, like all the other Mammalia then alive, either have become extinct or changed into a form that is no longer what it was before. As the evidence stands at present, man first appears on the earth in the Pleistocene age in that phase of the evolution of nature to which he belongs. The view of the higher antiquity of man based by M. Rutot on the presence of "eoliths," or chipped flints simulating the work of man in Eocene, Miocene, and Pliocene strata, is rendered untenable by the researches of Mr. Warren in this country and of MM. Boule and H. Breuil in France, who have proved that these forms can be, and in many cases have been, made by natural causes. These eoliths, therefore, cannot be used as anthropological documents in our inquiry.

The first starting point for our inquiry is presented by the discovery in 1894 of a skull and femur by M. Dubois in a Pleistocene river-deposit at Trinil, in Java, assigned by him to *Pithecanthropus erectus*, a form intermediate between the higher apes and man, and closely linked to the latter by the large brain and the erect gait. It is a veritable precursor of man, not only appearing at the point in the geological record where he might be expected, but in a tropical region taken by Lord Avebury and others to have been the birthplace of the human race. In Europe the implements and weapons of the Palæolithic hunter, associated with the bones and teeth of the animals that he hunted, afford ample proof of his presence in the caverns and in the river valley of the Pleistocene age over the whole region between the Mediterranean and the Baltic. The Palæolithic hunter presents two distinct phases of culture, those of the river-drift man and of the cave man, the former being the ruder and also the older, and the latter culminating in the wonderful artistic developments shown in the engravings, carvings, and painted frescoes of the caves of France and north-western Spain.

The conditions under which man found his way into Pleistocene Europe were strangely unlike those of to-day. The continent then extended southwards over the Mediterranean region, offering free passage to migration from northern Africa by way of Gibraltar and Sicily, and from Asia Minor by the elevation of the Ægean Sea and the Hellespont. On the Atlantic side the British Isles were united to France and Germany by the elevation of the beds of the intervening seas. On the east, too, a route of migration hitherto closed by a barrier of sea was offered to the Siberian fauna. The higher mountains were crowned with glaciers, and the climate was continental in character, with cold winters and hot summers. Under these geographical conditions the Pleistocene Mammalia invaded Europe both from the south and from the east and north-east at the close of the Pliocene age, and gradually took possession of the feeding grounds of the Pliocene fauna.

The invading forms may be divided into groups according to their present range, those that are now living (1) in temperate regions, (2) in northern, and (3) in southern climates. The first group, which includes most of the wild animals now living in middle and southern Europe, probably came from west central Asia. The second, including such Arctic species as the reindeer, musk sheep, and Arctic fox, came from the Siberian regions, and the third, represented by the lion, leopard, spotted hyæna, hippopotamus, caffer cat and others, came from the warmer regions, probably from northern Africa and perhaps Asia Minor. The extinct invading species, such as the mammoth and woolly rhinoceros, the cave-bear and the rest, also fall into one or other of these three groups. These animals ranged over the great Pleistocene continent, the northern so far to the south as the Alps and Pyrenees, and the southern over Spain and Italy, France and Germany, so far to the north as Yorkshire and Ireland, and both are found together in the caves and river deposits of the whole of central Europe and the British Isles.

There were, therefore, three distinct zones in Pleistocene Europe: the northern, into which no southern animal penetrated; the southern, in which no northern species is found; and the middle, extending from the Alps and Pyrenees over France, Germany, and the British Isles so far north as Yorkshire. In this the northern and southern forms were so mingled together that there can be no doubt that they lived at the same time. The spotted hyæna, for example, in the caves preyed upon the reindeer as well as the hippopotamus. This mixture of animals can only be explained by the migrating of these animals at different seasons in a continental climate with hot summers and cold winters, coupled with the secular changes in climate indicated by the development of an ice-sheet in the north and the spread of the glaciers over the lower valleys of the mountains.

The place of the river-drift man in these great migrations is clearly marked by his range. He came from the south, and his implements occur throughout the southern and middle zone so far to the north as Yorkshire. He also ranged in the Pleistocene age throughout northern Africa, Palestine, and Arabia into India, where he used the same implements as in Europe. He appeared and vanished along with the southern animals, and he lived in Europe during the time that the ice covered the higher grounds in the British Isles, as well as after the retreat of the ice from the districts which were covered during the maximum cold of the period.

The discoveries in the caves of Belgium, France, and Gibraltar establish the fact that the low type of river-drift man found in the Neanderthal cave ranged over those regions, and more recently Dr. Keith has noted it in the caves of Gibraltar. The river-drift man in Britain probably belonged to this primitive race.

The range of the cave man contrasts in every respect with that of the river-drift man. It is confined, with the solitary exception of the frescoed cave of Altamira, near Santander, to the region north of the Alps and Pyrenees, occupied by the northern group of Mammalia, the implements and weapons being met with in France, Belgium, Germany, and so far to the east as Moravia, and to the north as southern Yorkshire. They were successors of the river-drift men, and lived in the latest phase of the Pleistocene period.

Unfortunately, the caves of Great Britain throw no light on their physique. Nor are we helped in solving the problem by the caves of the Continent, because even if all the alleged discoveries be accepted, it does not follow that the same tribes lived in Britain. From the identity of their culture with that of the Eskimos, and from the fact that at various places in Siberia there are old camping grounds containing implements and the remains of the animals, both living and extinct, that are found in the caves of Britain and France, it is probable that the cave men have in remote times been in touch with the latter in northern Asia. The physical relations of the two peoples can only be decided by further discoveries in Europe, and especially by the archæological survey of Siberia. As the case stands now, the cave man probably came into Europe with the northern Mammalia from, and retreated with them into, northern Asia at the close of the Pleistocene period.

The Pleistocene period was undoubtedly of vast duration, and the antiquity of man is correspondingly great. It is to be measured by the sequence of geological events, by the changes in animal life, and by the advance in culture of successive races of mankind. It cannot be measured in years, because there are no chronometers in nature that record so small a unit of time. Outside history we

get a simple sequence of events following one another in due order, and with intervals of varying length, and these we are tempted to look upon without allowing for the perspective. The more minutely the events that have taken place since man appeared in Europe are examined, the more profound is the impression of the vastness of his antiquity and the futility of any attempt to compute it in terms of years.

THE DUKE OF THE ABRUZZI'S EXPEDITION TO THE KARAKORAM HIMALAYAS.[1]

THE expedition undertaken in the summer of 1909 by the Duke of the Abruzzi to the head of the Baltoro and the Godwin Austen glaciers in the Karakoram was essentially a mountaineering expedition. On the way out the longer summer route was followed across the Punjab Himalayas over the Zoji-La (11,230 feet), and down the valleys of the Dras and of the Indus, to Skardu, the capital of Baltistan. Here the route quits the Indus to ascend the Shigar and Braldoh valleys up to Askoley, the last inhabited spot, after which the glacier region is entered. While traversing Baltistan the expedition had the opportunity of seeing much of the Balti population and of photographing several groups of them. There can be no doubt that the great majority of the Baltis belong to the Aryan stock, and not to the Mongol-Thibetan, as has been stated by all English writers on the subject. The distinguished Hungarian anthropologist Ujfalvy had already demonstrated their close affinity to the Dards by comparative anthropometrical measurements.

A few miles above Askoley the Braldoh valley is intersected by the snout of the Biafo glacier. This glacier has undergone considerable variations in a recent period. In 1861, when Colonel Godwin Austen first visited it, it was wedged against the opposite or left bank of the Braldoh valley in such a way that the emissary stream of the Baltoro flowed through a tunnel underneath it. In 1892 Sir Martin Conway noted that it had withdrawn to such an extent as to leave free more than half of the valley, upon which it had deposited a deep layer of moraine. Since then the movement has again been forward, and in 1909 there were only from 200 to 300 yards between the snout and the rocks of the left wall of the valley.

On May 18 the expedition climbed up on to the Baltoro glacier. The snout of this glacier still corresponds absolutely with the description of it given by Conway in 1892. It may possibly be stationary, but certainly shows no sign of shrinking. All the tributary glaciers appear to be on the increase, and stretch out for a long distance on the top of the Baltoro, the surface of which they strew with broken seracs. Here angular measurements were taken, which were repeated two months later on the return journey, and established that the rate of motion of the centre of the glacier is on the average $5\frac{1}{2}$ feet a day during the months of June and July.

Later on the rate of the upper Godwin Austen glacier was observed. In the course of seven years the movement gave an average daily rate of barely 2 feet—considerably less than that of the lower Baltoro, although the grade is much steeper.

Near Rdokass were noticed on the glacier the strange pyramids of pure white ice which were first observed by Colonel Godwin Austen in 1861. At this point they appear as isolated cones, from 10 to 20 feet high; next as sharp pinnacles; and at last, higher up, as huge blocks from 100 to 150 feet in height, shaped like irregular prisms, and getting nearer and nearer together until they seem to be arranged in longitudinal rows.

The Karakoram range does not seem likely to offer an opportunity of solving the problem of the highest altitude attainable by man. The greater portion of the chain looks absolutely inaccessible. The difficulties of the ice and the rock are in most places so great that not even European alpine porters could carry up a load without the help of fixed ropes. This prevents the establishment of high camps, and was the obstacle which frustrated the Duke's one attempt to ascend K_2 by the rocky southeastern arête.

The exploration of the Godwin Austen glacier was completed by the end of June, and the Duke now decided to attempt the Bride peak (Karakoram No. 8 of T.S. of India, 25,110 feet), as being the highest and offering the additional advantage of having been trigonometrically fixed by the T.S. of India.

The Duke succeeded in establishing a camp on the Chogolisa saddle (20,778 feet), between the Golden Throne and the Bride peak. From this camp, an altitude of 24,600 feet, a little more than 500 feet below the summit, was reached on July 18.

The calculation of the altitude reached is based upon a barometric reading ($12\frac{9}{32}$ inches) referred to those taken on the same day at Skardu, Leh, Srinagar, and Gilgit.

The result of the survey is a map which comprises the upper basin of the Baltoro glacier, the whole of the Godwin Austen glacier, with its tributaries, which encircle three-fourths of K_2, and the mountain chains which enclose them. A number of new altitudes are given on the map. Of these, the most important is the one which assigns to the Broad peak an altitude of 27,133 feet. This altitude, added to that of Teram Kangri (27,610 feet), at the head of the Siachen glacier, brings up to seven the number of peaks now known to be above 27,000 feet. The other five are Mount Everest, K_2, the two peaks of Kanchenjunga, and Makalu.

The experience of this journey agrees with that of the Ruwenzori expedition in showing that the aneroid barometer is too delicate an instrument for mountain expeditions, and must be regarded as quite untrustworthy.

There is every reason to believe that the high regions of the Karakoram have a climate of their own which differs from that of the lower valleys, notwithstanding the shortness of distance as the crow flies. This experience confirms the observation recorded by previous explorers as to the absence of all electric phenomena in the atmosphere.

The expedition has recorded that the great chain of mountains comprising the Broad peak, the four Gasherbrums, and the Golden Throne, is composed of limestone and sedimentary rocks, whereas the opposite ranges, comprising the Staircase peak, K_2, and Bride peak, consist of crystalline rocks.

[1] Abstract of a lecture delivered before the Royal Geographical Society on November 21 by Dr. F. De Filippi.

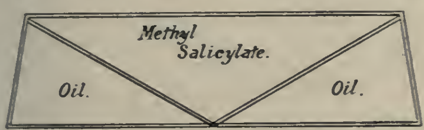
AHREN'S BILIQUID PRISM.

MR. C. D. AHRENS, the veteran prism-cutter, has lately devised a new type of liquid prism, which seems to have some advantages in optical work, both for direct-vision and for ordinary patterns of spectroscope. It is more than fifteen years since Wernicke proposed to employ in a direct-vision combination the highly dispersive liquid cinnamic ether. He found amongst modern sorts of optical glass one kind, a baryta crown, having the same mean refractive index, namely, 1·56, but having only about one-fifth as much relative dispersion. He was therefore able to make a flat-ended direct-vision prism by enclosing a glass prism of from 120° to 130° of refracting angle in a cell filled with the cinnamic ether, which thus constituted a triple combination, the glass prism being flanked by two reversed prisms of the ether. Several varieties of Wernicke's prism came into favour; but it had the drawback that cinnamic ether is expensive, and for some reason becomes cloudy after standing for a year or two in the containing cell.

More recently another highly dispersive organic liquid, also named by Wernicke, has found favour, viz. methyl salicylate. This substance has a mean refractive index of 1·5319, and its constringency (the reciprocal of its relative dispersion) is 24·7, as against 11·0 for cinnamic ether. Mr. F. Cheshire and others have used methyl salicylate with great success, in combination with reversed glass prisms, in apparatus that may be regarded as an improvement upon the prism of Wernicke. Methyl salicylate is, however, much cheaper than cinnamic ether, and does not become cloudy with lapse of time.

Mr. Ahrens has now produced a new type, the biliquid prism. It consists of a glass container divided by oblique partitions of thin plate glass into three triangular cells, one of which is filled with methyl salicylate, the other two with another liquid having a small dispersion relatively to

its refractive power. For the second liquid Mr. Ahrens has succeeded in finding in the paraffin series a white oil which is a suitable material in its mechanical as well as in its optical properties. It has not, however, the same mean refractive index as methyl salicylate, so therefore, for a direct-vision prism, the end faces cannot be square to the principal axis of the transmitted light. Their obliquity, however, is not great—not more than 15° if the refracting angle of the middle prismatic cell is from 120° to 125°. The dispersion of these prisms is very good, and there is much less absorption of the blue end of the spectrum than is usually found with a bisulphide or flint-glass prism. The writer, in a rough comparison of one of the Ahrens biliquid prisms with a Wernicke prism and a 60° bisulphide prism, found the following angular dispersions between



Ahrens's Biliquid Direct-vision Prism.

the C and F hydrogen lines:—bisulphide of carbon prism, 3° 27′; Wernicke prism, 3° 6′; Ahrens prism, 3° 12′.

If direct-vision is not desired, a prism of high dispersion can be made on the same biliquid plan by constructing a glass cell with the end faces at about 30° to the line of sight, and with internal oblique partitions at from 20° to 24° to the line of sight, dividing the whole into three prismatic chambers, the two outer of which are filled with methyl salicylate and the middle one with the white oil. This prism has marked superiority over a flint-glass prism of equal size. It must not, of course, be forgotten that all liquid prisms are unsuitable for fine definition of the spectral lines owing to the change of refractive index in the liquid when the temperature rises.

The biliquid prism is being put on the market by Mr. Pillischer.

THE REFORM OF MATHEMATICAL AND SCIENCE TEACHING IN GERMANY.[1]

THE revolt against formal culture which characterised mathematical instruction has within the last decade produced a large bibliography in English, French, and German, and inspired systematic inquiry into possible and needful reform. The movement has been assisted in Germany by an extension of the privileges of the Gymnasium to the Realgymnasium and the Oberrealschule, which in time may share the prestige of the Gymnasium and win for the exact sciences a place *ebenbürtig* with the classics.

When the Reformschulen were founded to provide a common foundation for all pupils in nine-class schools between the ages of nine and twelve, engineers were pronouncedly favourable, thinking that the exact sciences would benefit, and that an *Einheitsmittelschule* (secondary school with uniform curriculum) was in sight. But they were doubly disappointed; the classics have benefited, and the *Einheitsmittelschule* is condemned for systematic perfection.

Reform of mathematical and science teaching depends closely on the inexorable demands of civilisation, and for the understanding of modern culture a proper grasp of the meaning of a function is considered indispensable. On this account it is proposed to include analytical geometry and the calculus in the work of the nine-class schools. As no more time can be allotted to mathematics, any relief must come from further pruning of the syllabus. Hence elementary mathematics must be relieved of its lumber, the desire to achieve systematic perfection must be left unfulfilled, pedantic thoroughness must be killed by ridicule, and the exclusively deductive form abandoned, more value being attached to intuition than to a cunning use of the syllogism. Though mathematicians attack the isolation of their subject, they do not advocate *Fachbildung* (professional studies) in secondary schools. Professional bodies have always protested against it, and the protest has been taken to indicate the attitude of Trade Unions also. Nevertheless, German universities are trying to give the teacher an acquaintance with practical applications and arrange courses in applied mathematics or recognise attendance at technical high schools. The courses include descriptive geometry, mathematical methods of technical mechanics, surveying, life assurance, and laboratory work.

The introduction of practical work in the teaching of physics is urgently needed. It is provided in the best Prussian schools and in South Germany, notably at Munich, it forms part of the primary syllabus during the last two years. A statistical inquiry showed that 75 per cent., at least, of Prussian secondary schools desired facilities for experimental work, whilst only about thirty possessed them.

The minimum amount of time demanded is seven hours per week for science—physics, chemistry, biology, and geography—and four for mathematics. If proposals for introducing specialisation in the last three years are entertained, further hours may fall to the lot of the exact sciences.

The reintroduction of biology, which disappeared in 1879 as a result of the writings of Darwin and Haeckel, is being advocated as a training of the powers of observation, in which the German freshman is said to be woefully deficient, and as an exercise in the use of the microscope. Geography comprises economic geology, *Erdkunde*, and astronomy, as well as commercial products. To bring it into organic connection with mathematics, courses of lectures on the interconnection of mathematics are being projected.

Matters are still in an indefinite position, but there are indications that the Cambridge Congress of 1912 will mark the beginning of a new era. It is to be hoped, for our sakes, that the results of this congress can be laid before the Consultative Committee of the Board of Education to be recommended for adoption throughout the Empire.

[1] Abstract of paper read at the meeting of the Edinburgh Mathematical Society on November 11 by Mr. A. J. Pressland.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—Mr. John Dale has been awarded the Walter Myers studentship for a further period of one year, having proved himself a student of exceptional merit. An award of the same studentship for the present year has been made to Mr. Cranston Walker. The value of the studentship is 150*l*. per annum, and it must be used for research in pathology or clinical medicine at some German university. Mr. Dale, the first holder, is working at Hamburg, and Mr. Cranston Walker is at the University of Freiburg, in Baden. The holder must possess a degree in science in addition to degrees in medicine and surgery.

CAMBRIDGE.—An election to an Isaac Newton studentship will be held in the Lent term, 1911. It will be the duty of the student to devote himself during the tenure of his studentship to study or research in some branch of astronomy or of physical optics, according to a course proposed by himself and approved by the electors. The student's course of study or research must be pursued at Cambridge. The studentship will be tenable for the term of three years from April 15, 1911. The emolument of the student will be 200*l*. per annum. Candidates for the studentship are invited to send in their applications to the Vice-Chancellor between January 16 and 26, 1911, together with testimonials and such other evidence as to their qualifications and their proposed course of study or research as they may think fit.

Mr. A. E. Shipley, F.R.S., master of Christ's College, has been nominated by the general board of studies as a member of the board of electors to the professorship of zoology and comparative anatomy in succession to the late Mr. J. W. Clark; and Prof. W. J. Pope, F.R.S., has been nominated by the council of the Senate a member of the board of electors to the Allen scholarship.

OXFORD.—On November 22 another stage was reached in the discussion of the changes proposed by the Hebdomadal Council at the instance of the Chancellor of

the University. The preamble of a statute providing that Greek should no longer be a compulsory subject in Responsions was promulgated in Congregation, and on a division was rejected by 188 to 152. The form of statute was introduced on behalf of council by Mr. Matheson and opposed by Dr. James, president of St. John's College, and formerly headmaster of Rugby. Sir W. Anson, warden of All Souls', though not opposed to making Greek optional in certain cases, spoke against the proposal in its present form, a course which was also taken, on similar grounds, by Dr. Gilbert Murray, regius professor of Greek, and Mr. J. W. Mackail, professor of poetry. Mr. Cookson advocated the passing of the statute, and Prof. J. A. Smith argued on the same side. Mr. E. M. Walker opposed it. There is no doubt that the rejection of the preamble, which involves the loss of the statute, was largely due to the objection taken by Prof. Murray and the "moderate" party to the particular way in which the proposal had been framed. Rightly or wrongly, it was considered that no proper opportunity had been allowed for a fair discussion of possible limitations and alternatives, and the majority shrank from a measure that appeared to them unnecessarily drastic. Though for the present excluded by the vote of Congregation from the programme of university reform, it is not likely that the Greek question will be allowed to rest. But it must be remembered that, even if presented in a form acceptable to Congregation, the measure of relief has still to run the gauntlet of Convocation before becoming part of the statute law of the University.

IT is announced that an Imperial Conference on Education is to be held in London next year, probably in April. The conference is, it is said, to take place at the invitation of the Imperial Government, and is to be regarded as an outcome of the congress held in 1907 under the auspices of the League of the Empire. Delegates are expected from Canada, Australia, New Zealand, South Africa, India, and the Crown Colonies.

THE U.S. General Education Board, says *Science*, has made conditional appropriations amounting to 145,000*l*., distributed as follows:—Baylor University, Waco, Tex., 40,000*l*.; Trinity College, Durham, N.C., 30,000*l*.; University of Chattanooga, Tenn., 30,000*l*.; Meredith College, Raleigh, N.C., 10,000*l*.; Wesleyan Female College, Macon, Ga., 20,000*l*.; and Amherst College, Amherst, Mass., 15,000*l*. From the same source we learn that Wooster University has received 20,000*l*. from Mrs. J. S. Kennedy, of New York.

As has been stated in these columns, a Congress of the Universities of the Empire is to be held in London in 1912. On November 19 a meeting was held at the University of London, at which the Vice-Chancellors and other representatives of the universities of the United Kingdom were present for the purpose primarily of drawing up a paper of subjects for discussion at the congress. The subjects fell under the following heads:—(1) university organisation; (2) universities in their relation to teachers and undergraduate students; (3) universities in their relation to post-graduate and research work; (4) universities in their relation to schools and to other agencies for higher education. The draft agenda paper is to be sent at once to the various universities in the colonies and in India for comments and suggestions. The representatives of the Home universities will meet again early next summer to consider any representations made by the Colonial and Indian universities, and to select speakers to introduce the different topics to be discussed at the congress. It has been decided to hold the congress during the first week of July, 1912. We are glad to know that most of the universities throughout the Empire have accepted already the invitation to take part in what should prove an important and historic gathering. The secretary of the congress is Dr. R. D. Roberts, who may be addressed at the Congress Office, University of London, South Kensington, London, S.W.

LAST April Sir Henry Roscoe, F.R.S., as chairman of the Appeal Committee, made a public appeal for 70,000*l*. for providing new chemical laboratories at University College, London, including the purchase of the proposed site in Gower Place. The death of King Edward led to the postponement of the Mansion House meeting arranged, and this necessity gave a check to the work of the committee. Sir Henry Roscoe has now made a second urgent appeal, which has two objects: the first is to raise a sum of 25,000*l*. for the acquisition of the proposed site, the second to raise 45,000*l*. to erect the laboratories. The sum of 25,000*l*. must be raised before December 25 next if the Senate of the University is to be in a position to exercise the option which it holds to purchase the site. Towards this sum the committee has collected more than 9000*l*., leaving a balance of 16,000*l*. to be raised forthwith. The appeal is addressed especially to all those who realise the national importance of scientific research and its bearing upon the commercial prosperity of the country, to Londoners who desire to see university teaching in London developed in accordance with the needs of the nation, and also to the friends and admirers of Sir William Ramsay, the professor of general and inorganic chemistry at University College, to assist in this attempt to provide new chemical laboratories by gifts which will insure the acquisition of the site. It is earnestly to be hoped that the comparatively small sum of 16,000*l*. will be forthcoming before Christmas Day, so that the site adjoining the college, and eminently suitable for the proposed laboratories, may be secured. It may be pointed out that the number of students of chemistry at University College has increased greatly in recent years, and that the accommodation available has long been inadequate. The present laboratories were built in 1871, and to keep pace with modern requirements and to compete on something like equal terms with Continental universities a new building is required with up-to-date conveniences both for teaching and research. Donations should be addressed to Sir Henry E. Roscoe, F.R.S., at University College, Gower Street, London.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 17.—Sir Archibald Geikie, K.C.B., president, followed by Mr. A. B. Kempe, vice-president, in the chair.—Harold **Wager**: The effect of gravity upon the movements and aggregation of *Euglena viridis*, Ehrb., and other micro-organisms. *Euglena viridis* and some other micro-organisms, when placed in shallow vessels or narrow tubes in the dark, become aggregated into peculiar network-like patterns or more or less well-defined groups. In a narrow tube, placed horizontally in the dark, the aggregation takes the form of a series of groups which look like green bands crossing the tube from one side to the other. Each group shows a constant cyclic up and down movement, the denser central region moving downwards under the influence of gravity, and a lighter peripheral area consisting of organisms moving upwards, mainly by their own activity. The aggregation depends upon the number of organisms present, their activity, and the depth of the vessel in which they are contained, and may persist with its regular cyclic movements for several days. The downward movement appears to be a purely mechanical one, dependent upon the specific gravity of the organism, and is not due to a stimulus which evokes a physiological response, as in geotropism or geotaxis. The upward movement is, on the other hand, due partly to the activity of the organisms themselves, partly, no doubt, to the upward currents set up in the liquid by the friction of the downward-moving stream. The upward movement of Euglena is more or less vertical, and appears to be controlled, so far as the orientation of its elongate body is concerned, by the action of gravity. The aggregation resembles the cohesion figures produced when fine sediments are allowed, under certain conditions, to settle down slowly in a liquid, and are probably brought about much in the same way. The movements of certain micro-organisms are apparently controlled, therefore, in a purely mechanical fashion by gravity, combined with cohesive forces, and this is of advantage to species which, like Euglena, are often found in large numbers in a confined space, in that it prevents their accumulation in such dense masses as would be likely to interfere with their assimilatory and respiratory functions.—Miss Jean **White**: The

proteolytic enzyme of drosera.—L. S. **Dudgeon**, P. N. **Panton**, and H. A. F. **Wilson**: The influence of bacterial endotoxins on phagocytosis (including a new method for the differentiation of bacteria). Second report. The authors have failed to demonstrate in any of their experiments an action of the endotoxic substances on the leucocytes, and experiments leading to similar results were obtained by allowing bacteria to be exposed to the action of the specific endotoxic substances. They confirm the results published in the first communication, that the phagocytic result is dependent upon the interaction of endotoxin of serum. They have shown in the case of normal serum that the amount of phagocytosis permitted when bacteria and endotoxin interact is not related to the amount of hæmolytic complement present. The action of endotoxin appears to be specific even with bacteria so closely related as the typhoid and paratyphoid family. These results strongly suggest that this method can be employed for the differentiation of bacteria. The amount of endotoxin has been shown to be strongly thermostable.—S. B. **Schryver**: Some investigations on the state of aggregation of matter. Parts I.–III. *Part I. The action of salts in heterogeneous systems and the nature of the globulins.*—When complex substances, such as those which form colloidal solutions, enter into chemical reaction, the ordinary laws of chemical mass action are not always obeyed, the deviations therefrom depending upon the medium in which the reaction takes place. These are due to the adsorption of molecules from the medium on the surface of the large molecules of the colloid, which sterically inhibit chemical reaction. These conclusions were deduced chiefly by the study of the action of formaldehyde on Witte's peptone, whereby a methylene-imino derivative is formed, which readily, either by polymerisation or condensation between two molecules, forms an insoluble complex. The formation of this complex is inhibited by the presence of salts, the inhibitory action of a series of which has been quantitatively measured. The degree of inhibition was found to depend, in the case of monobasic sodium salts, on the physical properties of their aqueous solutions. The lower the surface tension and the lower the viscosity of the solutions, the greater the inhibitory action. The effect of surface tension could be deduced from the general study of adsorption phenomena, whilst the effect of viscosity could be deduced by the extension of the generalisations of Whitney and Noyes, and of Nernst as to the reaction rates in heterogeneous systems. The globulins, which are insoluble in water but soluble in salt solutions, are assumed to be complexes formed by the action of a basic group in one molecule with an acid group in another, by means of which a salt is formed, which undergoes slight but definite hydrolytic dissociation in the presence of water. In the presence of most salts, owing to adsorption by the dissociated globulin molecules, hydrolysis proceeds further than in presence of water alone, with the consequence that more globulin is dissociated and "dissolved." The solvent action of the salts here again depends upon the surface tensions of the solutions. Salts exert also a similar action in other heterogeneous systems in bringing about disaggregation, and the differences of solubility of various crystalline substances in salt solutions can be thereby explained. The physical constants of the salt solutions employed, and the solubilities of edestin and serum globulin in these solutions, are given. *Part II. The action of formaldehyde on Witte's peptone.*—The experimental details of this investigation are given. It is shown that the insoluble precipitate, formed by the interaction of the solutions, is derived chiefly from the more complex polypeptides. *Part III. The solubility of phenol and certain crystalline substances in salt solutions.*—The deductions as to the action of salts in heterogeneous systems are illustrated by the determination of the critical solution temperatures of phenol and salt solutions, which is a function chiefly of the surface tensions of the latter, and of the solubility of the following substances in salt solutions:—*d-l*-leucine, *d-l*-phenylalanine, caffeine, benzamide, and *p*-toluidine. The solubilities are affected by both the surface tensions and viscosities of the solutions.—F. W. **Twort**: A method for isolating and growing the lepra bacillus of man. Experiments were undertaken to obtain a method whereby the lepra bacillus of man and allied bacilli might be cultivated outside the body on artificial media. The material tested was obtained from a typical leper. Cultivations were made on ordinary laboratory media and on media containing extracts from animal organs and tissues; these gave negative results. In view of the close relationship between the tubercle bacillus and the lepra bacillus, it appeared highly probable that these two micro-organisms would require the same chemical substances for building up their protoplasm which could be elaborated from the ordinary media only by the tubercle bacillus. It was thought that if these substances could be supplied already formed to the lepra bacillus it might grow, and the easiest method of supplying these substances would be by adding to some good medium the ground-up bodies of the tubercle bacilli containing them; accordingly a medium was made as follows:—egg three parts, 0·8 per cent. sodium chloride one part, ground tubercle bacilli 1 per cent., and glycerine 5 per cent. or less, mixed, placed in tubes, sterilised, and set in slopes. Leprosy material was placed in 2 per cent. ericolin to kill contaminating micro-organisms, and then inoculated on the tubercle medium. On this the lepra bacillus grew very slowly as a delicate, colourless streak along the inoculated track, and showed the typical morphological and staining characters of the lepra bacillus; the bacillus could be sub-cultured only on the tubercle medium. Experiments will be made to prepare a lepra vaccine and to grow the lepra bacillus of rat. In conjunction with Mr. Ingram, the author has also succeeded in growing the bacillus found in Jöhne's disease of cows. It grows on the same medium, much like lepra bacillus, but somewhat faster. It is hoped soon to prepare a diagnostic vaccine for Jöhne's disease.—G. J. **Fowler**, E. **Ardern**, and W. T. **Lockett**: The oxidation of phenol by certain bacteria in pure culture. The investigation described in the paper arose out of a detailed examination of the effect of various antiseptic substances, including phenol, in bacterial sewage filters. It was found that the phenol apparently exerted a selective action on the bacteria present in the filtrate, only very few types appearing in the filtrate, more especially a liquefying organism (*B. liquefaciens fluorescens*) and a chromogenic organism. Pure cultures of these organisms were made, the medium generally used being ordinary peptone broth. The general method of experiment was to bubble air, under sterile conditions, through an aqueous solution of phenol to which a few c.c. of the culture were added. The strengths of phenol solution used varied from 8·4 to 16·5 parts phenol per 100,000 of water, and were determined by the oxygen absorbed from standard acid permanganate solution in three minutes. It was found that *B. liquefaciens* had no action, or only a very slight one, on phenol, even after exposure of a month or more, while on introduction of the chromogenic organism the phenol content diminished, slowly at first, and then, in two or three days, completely disappeared. In a final experiment, a solution was made use of containing 10 parts per 100,000 of phenol, together with the following ingredients:—

Ammonium sulphate...	...	0·1 grm.	per litre.
Potassium phosphate...	...	0·1 ,,	
Magnesium carbonate in suspension.	...	½–1 ,,	

After careful sterilisation this was inoculated with the organism, and incubated. After nine days the phenol had practically disappeared. Plate cultures were also made at the expiration of this time, and showed no evidence of the presence of more than one species of organism. The organism has been examined by Dr. Sidebotham, who concludes that it most nearly resembles *B. helvolus* (Zimmermann).

Mineralogical Society, November 15.—Prof. W. J. Lewis, F.R.S., president, in the chair.—J. H. **Collins**: Further notes on wood-tin. It is concluded that wood-tin, which always contains a good deal of iron oxide, and is much more opaque and more soluble than ordinary cassiterite, is the chalcedonic form, the shot-tin having had a concretionary, and the botryoidal form a stalagmatic, origin.—J. M. **Coon**: The alteration of the felspar of granites to china-clay. The action has taken place from within the earth towards the surface below the underground water-

level, the water outlets being generally indicated by schorl and quartz veins. The nature of the products of the alteration was discussed.—Prof. W. J. **Lewis**: Wiltshireite, a new mineral from the Binnenthal. The crystals were tin-white in colour, russet-brown when tarnished; small, but aggregated in parallel position, with monoclinic symmetry $a : b : c = 1{\cdot}587 : 1 : 1{\cdot}070$; $\beta = 100°\ 44'$. Paucity of material prevented a chemical analysis, but no doubt it is a lead sulpharsenite. Named after the late Rev. Prof. T. Wiltshire.—Arthur **Russell**: A new locality of phenakite in Cornwall. A single specimen showing numerous colourless prismatic crystals of phenakite was found by the author at Wheal Gorland, Gwennap, Cornwall, this year. The specimen was obtained from a lode at present worked for wolfram and traversing the granite close to its junction with the killas.

Institution of Mining and Metallurgy, November 16.—Mr. Edgar Taylor, president, in the chair.—A. Moncrieff **Finlayson**: Secondary enrichment in the copper deposits of Huelva, Spain. This paper embodies the results of an investigation of variations in the ore-content of the lodes in the mining district named, with subsequent microscopic examination of the ores, with the view of determining the paragenesis of the minerals and the nature and extent of alteration. The following general conclusions were arrived at:—that the copper in the pyrites occurs primarily as a definite mineral (chalcopyrite), and is not chemically combined with the pyrite; that the order of deposition of the primary minerals was pyrites, chalcopyrite, blende, galena; that the processes of secondary enrichment consist, in lean ores, in a change from chalcopyrite to chalcocite, and in richer ores in a gradual aggregation of secondary chalcopyrite accompanied by chalcocite; that the preliminary changes due to enrichment extend to considerably greater depths than is indicated by the percentage composition of the ore. The characteristic process is undoubtedly the formation of chalcocite from chalcopyrite, chalcocite being formed, in part at least, during the oxidation of the leached heaps.—J. Bowie **Wilson**: Notes on the Mount Morgan ore deposits, Queensland. This paper is a brief account of the development of these deposits, brought up to date, the latest of previous technical papers on the subject being at least ten years old. Considerable space is devoted to a consideration of the geology of the deposit. The author considers that the deposit was formed in an area of country rock much shattered by intrusive dykes, which has allowed free circulation of ascending mineral-bearing solutions, the mineralisation occurring simultaneously with metamorphism of the original sedimentary rocks forming a background to the deposit. He admits, however, that there are several phenomena which do not absolutely fit in with his theory.—D. M. **Levy**: The successive stages in the bessemerising of copper mattes as indicated by the converter flame. This paper, which is accompanied by four coloured plates reproduced from Lumière photographs, deals with the two main stages in the process of bessemerising copper mattes, the "slagging" stage, during which the iron-sulphide is eliminated, and the second stage, during which the sulphur is finally eliminated, the slag being poured off and the white metal blown up to blister copper. The colours of the flames at these two stages are characteristic, and there are other points, at first blowing and at the end of the slagging stage, when the flame colour is equally indicative of the stages reached in the complete operation. The author follows out the process in detail, and appends observations made during a typical "blow."

Royal Meteorological Society, November 16.—Mr. H. Mellish, president, in the chair.—Miss M. **White**: Results of the hourly balloon ascents made from the Meteorological Department of the Manchester University, March 18–19, 1910. Twenty-eight small rubber balloons carrying Dines's meteorographs were liberated hourly, and of these twenty have been recovered. The balloons left Manchester going at first in a southerly, and later south-easterly, direction, and were found in the Worcester, Hereford, and Monmouth districts, one reaching North Devon. The direction of the upper wind was constant during the period over which the ascents extended, and did not vary with height. The average height of the stratosphere was 10·7 km. Whereas at the ground level the temperature was remarkably constant throughout the course of the experiments, showing a maximum variation of fewer than 2° from the mean, the isothermals at the higher levels show a well-marked rise throughout the first fifteen hours; *e.g.* a temperature of −40° C. was at first encountered at a height of 6 km., but continued to recede, until at the end of twelve hours it was not met with until 8 km. height.—W. H. **Dines**: Results obtained from the registering balloon ascents carried out during the two international weeks, December 6–11, 1909, and August 8–13, 1910. Balloons on each occasion were sent up from Manchester, Pyrton Hill, Ditcham Park, Crinan in Scotland, and also in the west of Ireland. Seventeen records were secured in the December ascents, and these show that the value for the height of the isothermal column or stratosphere are some of the lowest ever observed, and the temperatures are perhaps the lowest ever recorded, at a height of 5 miles. Of the balloons sent up in the August week seventeen were found. The average height attained was about 10 miles. The inversion of temperature at the commencement of the isothermal layer was larger than usual.—C. J. P. **Cave**: Pilot balloon observations made in Barbados during the international week, December 6–11, 1909. These observations, which were undertaken at the request of the Royal Meteorological Society, were carried out by Mr. Radcliffe Hall and several other gentlemen associated with him. The prevalence of clouds during the daytime interfered with the ascents, many of the balloons being lost to sight after a few minutes. It seems that the wind behaves like an east wind in this country, increasing to a maximum and then falling off above.—W. **Marriott**: Three registering balloon ascents carried out at the Royal Agricultural Society's Show at Liverpool on June 21–23.—Captain C. H. **Ley**: The irregularities of the wind at moderate altitudes.

CAMBRIDGE.

Philosophical Society, October 31.—Prof. Hobson, vice-president, in the chair.—Sir J. J. **Thomson**: A new method of investigating the positive rays. In this method the rays are received on a photographic plate inserted inside the discharge tube, and placed in a light-tight case until it is wished to photograph the rays, when the plate is lifted from its case by a mechanism worked from the outside, and the rays are allowed to fall upon it. It is found that a photographic plate is very sensitive to the rays; a pencil of these only one-third of a millimetre in diameter gave a good photograph in less than five minutes. The photographic plate, besides being much more sensitive than the willemite screen hitherto used by the author, has the advantage of giving a permanent record and allows of greater accuracy of measurement. Using this method, the author has detected in the positive rays, in addition to the atom and molecules described in his paper in the October number of the *Philosophical Magazine*, positive rays of a secondary nature having values of m/e, 1·5, 2·5, &c., that for the hydrogen atom. Photographs taken by this method were exhibited at the meeting.—R. **Whiddington**: Preliminary note on the properties of easily absorbed Röntgen radiation.—R. T. **Beatty**: The ionisation of heavy gases by X-rays. When X-rays pass through matter their energy is absorbed in the production of δ, β, and γ rays. X-rays the absorption of which in aluminium ranged from $\lambda = 230$ to $\lambda = 4$ were passed through AsH_3 and SeH_2, and the absorptions in these gases were measured. It was found that β and γ rays occurred together when the characteristic γ radiation of SeH_2 was excited. On subtracting the increase in ionisation due to these rays, the ionisation due to the direct formation of δ rays, relatively to the ionisation in air, remained constant for all the radiations used. It thus appears that the processes which go on when the characteristic radiation is produced do not alter the rate at which direct ionisation takes place in the gas. Incidentally, Lenard's law of absorption of corpuscular rays is confirmed to a few per cent.—S. G. **Lusby**: The mobility of the positive ion in flames. The mobility of the positive ions due to salt vapours in a flame was determined in these experiments. It was found that for all salts of all metals of the alkali and the alkaline earth groups this mobility was a constant

quantity, and at a temperature of 1500° absolute was 290 cm. per second. From a theoretical formula it was further deduced that the ion at this temperature had the mass of a hydrogen atom. Experiments are proceeding to test further this latter result.—G. W. **Todd**: Mobility of the positive ions in gases at low pressures. By an adaptation of Rutherford's alternating field method, the mobilities of the positive ions produced in gases by means of X-rays have been measured between pressures of 1 and 25 millimetres of mercury. Unlike the negative ions, no change was observed in the law that the product of the pressure and the mobility is constant for the same gas. Further experiments are in progress with the positive ions given off from aluminium phosphate.—G. H. **Hardy**: Fourier's double integral and the theory of divergent integrals.

PARIS.

Academy of Sciences, November 14.—M. Émile Picard in the chair.—The president announced the death of M. Tannery, free member of the academy.—M. L. Teisserenc de Bort was elected a member in the place of M. E. Rouché.—A. **Perot**: The spectroscopic measurement of the rotation of stars possessing an atmosphere, with special reference to the sun. A mathematical investigation showing that, in the absence of knowledge as to the true direction of the light ray at the point where it meets the reversing layer and of its propagation in the layers through which it then passes, caution is needed in translating radial velocities into velocities of rotation.—M. **Javelle**: Observations of Halley's comet made at the Nice Observatory with the Gautier equatorial of 76 cm. aperture. Observations are given for November 3, 8, 10, 11, and 12, together with the positions of the comparison stars. The comet was extremely faint, being reduced on November 3 to a vague white spot about 1′ in extent, without visible condensation.—P. **Chofardet**: Observations of Cerulli's comet (1910*c*) made at the Observatory of Besançon with the bent equatorial. Data are given for November 10, 11, and 12. The comet appeared as a round nebulosity 30″ to 40″ in diameter, and was estimated to be of the eleventh magnitude.—M. **Coggia**: Observation of Cerulli's comet made at the Observatory of Marseilles with the Eichens equatorial of 26 cm. aperture. Data given for November 11.—Louis **Bachelier**: The movement of a point or material system submitted to the action of chance forces.—M. **Arnodin**: The bridge at La Cassagne (Gisclard system). An account of a suspension bridge of a new type constructed on the electric railway over the Pyrenees between Villefranche and Bourg.—Madame M. **Dussaud**: Discontinuous sources of light. A commutator is fixed on to the mechanism of a kinematograph in such a manner that the lamp is extinguished during the time that a forward step is made by the film, the latter being only illuminated when stationary. The advantages of this arrangement are enumerated.—Jean **Becquerel**: Polarised phosphorescence and the correlation between the polychroïsm of phosphorescence and the polychroïsm of absorption. An account of experiments on the phosphorescence of rubies at low temperatures (the boiling point of nitrogen). A change in the orientation of the exciting rays results, not in a change in the state of polarisation of each line, but a variation in the intensity emitted, and this variation may vary from one line in the spectrum to another. These results necessitate a modification of the views previously admitted.—A. **Cotton** and H. **Mouton**: The absolute measurement of the magnetic double refraction of nitrobenzene. Comparing the method previously described by the authors and that of Skinner on the same subject, a source of error has been discovered in the latter, and, allowing for this, both sets of measurements are in good agreement.—Edmond **Bauer** and Marcel **Moulin**: The blue colour of the sky and the constant of Avogadro. According to a theory of Lord Rayleigh, the blue colour of the sky is due to the dispersion of sunlight by the molecules of the air, and from this theory an expression is deduced giving the Avogadro constant N (the number of molecules in the gram-molecule), in terms of the ratio e/E (brightness of the sky to that of the sun), the dielectric constant of the air, the apparent diameter of the sun, and other measurable data. The measurement of the ratio e/E is the most difficult, too large a value being found in the presence of large particles. An account is given of determinations of this ratio carried out in August, 1910, at the Vallot Observatory at the summit of Mt. Blanc. The weather was unfortunately unfavourable, but the figures obtained were of the same order as those of Rutherford and J. Perrin, based on different considerations. The results are favourable to Lord Rayleigh's theory.—A. **Lafay**: The inversion of the Magnus phenomenon.—F. **Michaud**: A capillarimeter for the measurement of the surface tension of viscous liquids. The capillary tube is bent at right angles, and the horizontal portion placed just under the surface of the liquid. The liquid is brought to a fixed mark on the horizontal portion by the pressure of an indiarubber ball, and the hydrostatic pressure then measured.—L. **Grenet**: The tempering of bronze.—M. **Barre**: The double sulphates formed by the sulphates of lanthanum and cerium with the alkaline sulphates.—J. **Taffanel**: Safety explosives employed in mines. An account of experiments carried out at the testing station of the Central Committee of French Collieries. The results obtained showed the importance of freeing the hole from coal-dust before fixing in the cartridge; that paraffined paper as an envelope for the cartridge produced injurious effects was also made clear by these experiments.—A. **Besson** and L. **Fournier**: The reduction of phosphoryl chloride by hydrogen under the influence of the silent discharge. The main reaction is the formation of the oxide P_2O, hydrochloric acid, and water.—Marcel **Delépine**: The action of pyridine upon the iridodisulphates.—G. **Guillemin** and B. **Delachanal**: Research on the gases occluded in the copper alloys. The metals examined included various kinds of brass, bronze, phosphor bronze, and tin, and the gases were only given up after fusion in a vacuum. Carbon dioxide and hydrogen were present in all the metals examined, methane and carbon monoxide being also present in the majority of cases.—G. **Darzens**: A new method for the preparation of the glycidic esters. Ethyl dichloroacetate and acetone react readily in benzene solution with magnesium, α-chlor-β-oxyisovalerianic ethyl ester being formed. From this the theoretical yield of dimethylglycidic ethyl ester is readily prepared in theoretical yield by treatment with sodium ethylate.—Gabriel **Bertrand** and G. **Weisweiller**: The constitution of vicianose and vicianine.—Ch. **Mauguin**: Liquid crystals in convergent light.—Méd. **Gard**: A hydrid of *Fucus platycorpus* and *F. ceranoides*.—Lucien **Daniel**: A perennial bean.—Jules **Amar**: The working of the human machine.—A. **Fernbach** and M. **Schœn**: The influence exerted by the reaction upon certain properties of malt extracts. The extracts were made neutral to different indicators, and the resistance to the effect of a rise of temperature and the increase in diastatic activity after keeping were measured.—L. **Launoy**: The toxicity of some mineral and organic compounds of arsenic: effect of repeated non-toxic doses.—Louis **Léger**: The muddy taste in certain fresh-water fish.—J. **Deprat**: The tectonic of Yun-nan.—Th. **Glangeaud**: The western edge of the Montbrison basin.—F. **Grandjean**: A measure of the lamination of sediments (limestones and schists) by means of the tourmaline crystals.

NEW SOUTH WALES.

Royal Society, June 1.—Mr. H. D. Walsh, president, in the chair.—G. H. **Knibbs**: Note on the influence of infantile mortality on birth-rate.—L. **Cohen**: The determination of alkali in arsenical dip-fluids.—Prof. A. C. **Haddon**: Note on Mr. L. Hargrave's paper, "Lope de Vega."—T. Harvey **Johnston**: Australian avian entozoa.—T. W. **Keele**: The great weather cycle.

July 6.—Prof. T. W. E. David, F.R.S., president, in the chair.—A. **Duckworth**: The respective limits of Federal and State legislation in regard to companies.—J. H. **Maiden**: Records of the earlier French botanists, as regards Australian botany.—Dr. W. G. **Woolnough**: Stone rolls, in the Bulli coal seam of N.S. Wales.—Dr. J. Burton **Cleland** and T. Harvey **Johnston**: Worm-nests in Australian cattle due to *Filaria* (*Onchocerca*) *gibsoni*, with notes on similar structure in camels.—T. Harvey **Johnston** and Dr. J. Burton **Cleland**: The anatomy and possible mode of transmission of *Filaria* (*Onchocerca*)

gibsoni.—C. F. **Laseron**: Palæontology of the Lower Shoalhaven River.

August 3.—Prof. David, F.R.S., president, in the chair.—A. **Duckworth**: White Australia.—Dr. J. Burton **Cleland** and T. Harvey **Johnston**: The hæmatozoa of Australian batrachians, No. 1. In this paper the authors give a list of frogs which were searched for the presence of hæmatozoa. In ten species, represented by thirty-four specimens examined, the results were negative, while in three species, represented by seven specimens, blood parasites were detected. A hæmogregarine, *Haemogregarina* (*Lankesterella*) *hylae*, infesting *Hyla caerulea* is described as new, and a trypanosome from *Lymnodynastes tasmaniensis* and *L. ornatus?* is regarded as being similar to, though probably not identical with, *Trypanosoma rotatorium*.—E. C. **Andrews**: An excursion to the Yosemite, or studies in the formation of Alpine cirques, steps, and valley treads. In a previous report (corrosion by gravity streams) the writer gave a general account of stream corrosion. In the present paper a more detailed account is given of the origin of the cirque, and the "steps" and "treads" of Alpine Valley. A special application of the principle put forward is made to the case of the Yosemite and associated valleys in California.—T. Harvey **Johnston** and Dr. J. Burton **Cleland**: A note on the occurrence of pentastomes in Australian cattle. In a short note the authors deal with the finding of larval pentastomes (*Linguatula serrata*) in the mesenteric glands of a number of cows in the Illawarra district. The hosts were all affected with endemic hæmaturia, and the discovery of these parasites suggests that they may perhaps play a rôle of much economic importance.—H. G. A. **Hardinge**: The condition of the atmosphere during the recent proximity of Halley's comet. Analyses were made of the atmosphere collected at an elevated locality in the neighbourhood of Hornsby about a week previous to the supposed date of contact (May 19) until a week following that event. There were no appreciable differences noted in the composition of the air during the whole of this time, neither did spectroscopic examination reveal any peculiarities.

Calcutta.

Asiatic Society of Bengal, November 2.—Panchanan **Neogi** and Birendra Bhusan **Adhicary**: Reactions in presence of nickel. (*a*) Inability of nitrogen and hydrogen to combine in presence of iron and nickel. (*b*) Reduction of the oxides of nitrogen, sulphur, and phosphorus in presence of nickel. Johnson showed that nitrogen and hydrogen combine directly to form ammonia in presence of heated spongy platinum. This was contradicted by Wright, who showed that the ammonia obtained by Johnson was due to the reduction of traces of nitric oxide contained in nitrogen. Ramsay and Young showed that traces of ammonia are formed by the direct combination of nitrogen and hydrogen in presence of red-hot iron filings. The authors show, however, that the two gases *do not* combine at all, provided the nitrogen is rendered absolutely free from nitric oxide and iron from carbon. It has also been shown that ammonia is not formed by passing the mixed gases over heated nickel. It is further shown that nitric oxide, sulphur dioxide, and phosphorus pentoxide are reduced to the corresponding hydrides by means of hydrogen in presence of reduced nickel. The mechanism of the reactions has also been studied.

DIARY OF SOCIETIES.

THURSDAY, November 24.

Royal Society, at 4.30.—On the Sequence of Chemical Forms in Stellar Spectra: Sir Norman Lockyer, K.C.B., F.R.S.—The Influence of Viscosity on the Stability of the Flow of Fluids: A. Mallock, F.R.S.—On Atmospheric Oscillations: Prof. Horace Lamb, F.R.S.—A Theory of the Chemical Action of the Electric Discharge in Electrolytic Gas and other Gases: Rev. P. J. Kirkby.—An Electrostatic Voltmeter for Photographic Recording of the Atmospheric Potential: G. W. Walker.—Optical Dispersion, an Analysis of its Actual Dependence upon Physical Conditions: Dr. T. H. Havelock.—The Spectrum of Halley's Comet: C. P. Butler.—A Geometrical Proof of the Theorem of a Double Six of Straight Lines: Dr. H. F. Baker, F.R.S.

Institution of Electrical Engineers, at 8.—Street Lighting by Modern Electric Lamps: H. T. Harrison.

FRIDAY, November 25.

Physical Society, at 5.—The Electric Stress at which Ionisation begins in Air: Dr. A. Russell.—The After-glow produced in Gases by Electric Discharge: Prof. the Hon. R. J. Strutt, F.R.S.—Exhibition of a Surface-brightness Photometer: J. S. Dow.—The Approximate Solution of various Boundary Problems by Surface Integration combined with Freehand Graphs: L. F. Richardson.

MONDAY, November 28.

Royal Society of Arts, at 8.—Industrial Pyrometry: C. R. Darling.

Institute of Actuaries, at 5.—Inaugural Address by the President: G. H. Ryan.

TUESDAY, November 29.

Royal Anthropological Institute, at 8.15.—Certain Physical Characters of the Negroes of the Congo Free State and Nigeria: Dr. A. Keith.—The Search for the Original Home of the Maori: A. W. Newman.

Zoological Society, at 8.30.—On a Possible Cause of Pneumo-enteritis in the Red Grouse (*Lagopus scoticus*): Dr. H. B. Fantham and H. Hammond Smith.—On the Alimentary Tract of certain Birds, and on the Mesenteric Relations of the Intestinal Loops: F. E. Beddard, F.R.S.—On the Specimens of Spotted Hyænas in the British Museum (Natural History): Prof. A. Cabrera.—The Development of *Solaster endeca* Forbes: Dr. J. F. Gemmill.

Royal Society of Arts, at 4.30.—The Progress and Prospects of Mining in Western Australia: A. Montgomery.

Institution of Civil Engineers, at 8.—*Further discussion*: Portland Cement, and the Question of its Aeration: H. K. G. Bamber.

WEDNESDAY, November 30.

Royal Society of Arts, at 8.—Argentina from a British Point of View: Campbell P. Ogilvie.

British Astronomical Association, at 5.

THURSDAY, December 1.

Linnean Society, at 8.—Spermatogenesis in Stenobothrus: Capt. C. F. U. Meek.—Reports on the International Botanical Congress at Brussels, 1910: Dr. Otto Stapf and others.

Röntgen Society, at 8.15.—Osmotic Growths: Dr. Deane Butcher.

HISTORY IN BRITISH PLACE-NAMES.

British Place-names in their Historical Setting. By Edmund McClure. Pp. 349. (London: Society for Promoting Christian Knowledge, 1910.) Price 5s.

THE loving labour of an average lifetime, "studies in leisure hours extending over some thirty years and more," this work is an eloquent testimony to the value of the science of philology in the elucidation of historical materials. It is both a history and a valuable guide to the philology of British place-names "as they occur chronologically in authentic historical documents from 54 B.C. until A.D. 1154." In his last paragraph, the author explains why he draws a line at Stephen's death.

"The consideration of later records containing place-names is not worth pursuing, as the forms therein presented vary but little from those now in use, and the new terms introduced by the continental monastic orders, such as *Beaulieu, Rievaulx, Jervaulx,* &c., explain themselves" (p. 304).

The phrase "not worth pursuing" surely needs some qualification, and the explanation offered implies that the author is satisfied that later documents contain no material additions to his list of historical place-names.

Very appropriately, "a short summary of the modern methods employed in linguistic research" is given at the beginning, to "illustrate the statement in the text and show the truly scientific character of comparative philology" (p. 13). The text is mainly a history of Britain with the place-names worked in, the latter elaborately discussed in "notes" and footnotes. The thoroughness, as well as the duration, of the author's studies are well attested by the numerous catenæ of name-forms. The best authorities on place-names are cited. Yet the author exhibits throughout a commendable critical independence, as well as personal detachment from pet theories, or theories one would have liked to press from personal conviction. When he discusses rival theories, as in the case of the Picts and their language, he gives a clear idea of the situation.

Considering the great advance made in philology and historical criticism in the last thirty years, such a work as this is must have been periodically revised to a large extent. Specialists in certain lines of inquiry would have expected further revision of some of the information given. The author betrays a suspicion of the genuineness of Gildas's "Destruction of Britain," the spuriousness of which has recently been demonstrated by Mr. Wade Evans and others. In the discussion of sites of battles fought by Arthur, no reference is made to Mr. Anscombe's clever elucidation of the place-names. Sir John Rhys is, of course, the most frequent witness in the author's court, but while the latest edition of the classic "Celtic Britain" has been consulted, no reference is made to that eminent scholar's contributions to the British Academy and the Cymmrodorion Society within the last seven years or so. The author's remark that "the nucleus of the work has already appeared in a serial" sufficiently accounts for the belatedness, in these expeditious days, of some sections of the work. Finality in a work of such a comprehensive design is out of the question, and such omissions as those noted above affect only very slightly the unquestioned usefulness of the work as it is.

The author seems to have a very firm grip of the Scandinavian element in British place-names, a subject which is coming more and more to the fore. In his discussion of the place-names of Shetland and the Orkneys, which are "almost exclusively Scandinavian" (p. 227), the author leaves an impression that he is unwilling to go as far as his evidence goes, and one's attention is arrested by a doubtful deduction.

"As *Orkn* in Norse means a seal, Orkn-eyjar would seem a natural designation for these islands, but the term *Orc* in Orcades goes back to classical times, long before a Northman had put his foot upon them, and its meaning must be sought in the language of the earliest inhabitants" (p. 225).

The facts cited favour a theory of a very early occupation of the Orkneys by Scandinavians, and other evidence may be adduced to the same effect, but all that evidence must be laid aside, because the author is satisfied with some late date for such occupation, and with "classical" spellings of place-names in Britain. On general grounds, alleged dates of the beginnings of great racial migrations are open to a reasonable suspicion, and "classical" references to places in Britain cannot be accepted as final as against overwhelming local evidence.

The perusal of this scholarly, yet readable, book, in which history and philology are made to eludicate each other, opens up a vast field of inquiry, in which archæology, anthropology, and astronomy should also be requisitioned. We have given us an estimate of the value of documentary place-names. A companion volume on the documentary value of place-names in current use, or unrecorded in the documents examined by the author, would be very acceptable. The book is a marvel of compression, and an index of forty-five pages makes it a most welcome work of reference.

JOHN GRIFFITH.

THE CHEMISTRY OF THE ALKALOIDS.

Die Alkaloide. By Prof. E. Winterstein and Dr. G. Trier. Pp. vii+340. (Berlin: Gebrüder Borntraeger, 1910.) Price 11 marks.

SINCE Derosne and Sertürner isolated morphine, the crystalline principle of opium, about a century ago, the separation of the natural bases from plants has always taken a prominent place in chemical research. To-day the number of these substances exceeds two hundred, and the list is probably far from complete. The process of their isolation is usually accompanied by a study of their therapeutic value and by the more difficult and fascinating task of discovering their structure. Of the pioneers in this branch of chemistry, A. W. Hofmann stands in the forefront. Following the earlier discoveries of Gerhardt on the relation of the pyridine bases to the alkaloids, he was able by the aid of new and ingenious methods of dis-

integration, to identify many of the products with derivatives of these bases. But, as the authors of the above monograph state :—

"The constitution of an alkaloid cannot be regarded as definitely ascertained until it has been artificially prepared in accordance with the formula and identified with the natural product."

It is this last synthetic process which calls for the utmost resource and skill of the experimenter. The success which accompanied Hofmann's researches only served to emphasise the difficulties of the final synthetic stage. In spite of the magnitude of the task, Ladenburg accomplished the complete synthesis of coniine (the active principle of hemlock) in 1886. This was followed by Hantzsch's synthesis of trigonelline in the same year, and of piperine by Ladenburg in 1894. Perhaps the most brilliant of recent achievements in this region of research are the syntheses of the tropine alkaloids (atropine, cocaine, tropacocaine) by Willstätter, laudanosine, papaverine, and nicotine, by Pictet, and the purine bases by E. Fischer.

As it is improbable that any known alkaloid exceeds in complexity those the synthesis of which has been accomplished, it may be safely predicted that sooner or later all will be produced artificially. Interesting as this record is of past results and future promise, the real significance of these discoveries is much more far-reaching; for the peculiar physiological properties of the alkaloids has led directly to the study of the relation of atomic grouping to physiological action. The ceaseless activity which has been displayed in this direction, especially in the German laboratories, has thrown so much light on the subject that new drugs are constantly produced the therapeutic action of which closely imitates that of the natural product. This vast and ever-increasing mass of new observations has already been carefully compiled in a treatise by Pictet, and in several monographs by Schmidt.

With the exception of one chapter on the source and significance of the alkaloids in plant-life, to which reference is made below, there is nothing in the present volume which can be said to supersede those named. Like the latter, it is a compilation of the more important facts systematically arranged and brought up to date; but there is no attempt at literary embellishment, which renders Pictet's book so readable, nor are those full references given, which are indispensable in a book of this nature, and form so important a feature in its predecessors. The concluding chapter on the origin of the alkaloids in the plant is the most interesting in the book, not because it throws much new light on the problem, but rather because it reveals the enormous difficulties which surround it. The authors rely on the proteins for their raw material, which, it is well known, contain no pyridine, quinoline, or isoquinoline constituent. For these nuclei they have recourse to such protein products as lysine and arginine, which can conceivably be fused into rings and bring to their aid formaldehyde, and its reduction and oxidation products, methyl alcohol, and formic acid for further elaborating these simpler ring compounds. Theorising is a necessary part of every progressive science, and no fault need be found with the authors if they like to exert their ingenuity on so fascinating a theme. At the same time, it may be pointed out that, if protein materials are to be taken as the starting point, the origin of such compounds as tyrosine and tryptophane affords difficulties quite as great as those which surround the natural synthesis of the alkaloids.

J. B. C.

PRACTICAL GARDENING.

Manual of Gardening. A Practical Guide to the Making of Home Grounds, and the Growing of Flowers, Fruits, and Vegetables for Home Use. By L. H. Bailey. Pp. xvi+539. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 8*s.* 6*d.* net.

PROF. BAILEY is already very well known to readers in this country as the author of numerous works upon various branches of scientific horticulture. His greatest work is a "Cyclopædia of American Horticulture," in several large volumes, and containing an immense amount of information on American garden plants, contributed by a large number of specialists. The present work, though far less ambitious, will be found extremely useful to gardeners in the States, even to those with very little experience, for the author, specialist as he is, finds no difficulty in writing upon garden subjects in a manner easily understandable by amateurs.

In a large measure the work is a combination and revision of two former volumes, "Garden Making" and "Practical Garden Book," and it constitutes a guide to the making of home grounds, and the growing of flowers, fruits, and vegetables for home use.

Gardening in the States is not so general or technical as it is in our own country, and most of those who attempt to practise it find a great difficulty at the very outset, for they have few good models available to inspire them with correct ideas. In a large number of instances the formal method of design and planting is given preference, and the ordinary formal garden in America has most of the blemishes such gardens possess at home, but few of the virtues that characterise this system of landscape gardening at its best. There are certain instances of first-rate formal gardening in America, but, as the author of "The American Flower Garden" pointed out recently, the public has seldom the opportunity to inspect them.

Prof. Bailey's advice on the formation of gardens is therefore very opportune, for whilst he does not show himself as a partisan of either of the opposed methods, he explains carefully and in great detail how to make the best use of both by adopting them to the special circumstances of site, aspect, altitude, soil, and climate. Having discussed the "point of view" with regard to laying out the garden and planting it, the author proceeds to relate in detail the treatment of the more important species of plants. The chapter on the protection of plants from things that prey upon them (pests) is unusually valuable, for Prof. Bailey has a rare experience of the subject. Chapters ix. and x. deal respectively with fruit and vegetables, and on these subjects cultural details are supplied on almost every crop. The crops are much the same as

our own; indeed, the fruit crops are identical, whilst all our well-known vegetables are included amongst those cultivated in America, but there are some which are not familiar to us, including such as the sweet-potato, Rutabaga (a kind of turnip), watermelon, pepper, and okra. The okra is a plant belonging to the cotton family, and the green pods are used for making the well-known gumbo soup common in the southern States. The pods are also used for stews, and they are preserved by drying for use in winter.

The book concludes with a chapter containing cultural reminders for every month in the year, both for the northern and southern States, the requirements differing somewhat widely owing to the great differences in the climate.

The volume is freely illustrated, and it contains twenty-five plates which are reproductions from photographs. Beyond these there are numerous illustrations in the text, most of them from sketches, and, taking them generally, they are very inferior, the figures of apples and other fruits being particularly inadequate and disappointing.

A TREATISE ON BRITISH NUDIBRANCHIATE MOLLUSCA.

A Monograph of the British Nudibranchiate Mollusca, with Figures of the Species. Text by Sir Charles Eliot, K.C.M.G. Figures by the late Joshua Alder and the late Albany Hancock and others. Part viii. (Supplementary). Pp. vi+197+8 plates. (London: The Ray Society and Dulau and Co., 1910.) Price 25*s.* net.

THIS "supplement" to a work issued half-a-century ago has been admirably conceived and written by the Vice-Chancellor of Sheffield University. Alder and Hancock's classic monograph is known to every marine zoologist, and fifty years of research and criticism have found scarcely one weak place or error in that accurate and beautiful treatise. The authors, however, had accumulated certain addenda which they would probably have eventually published in the present form of a supplement. They knew that certain of their descriptions were not sufficiently full or were not based on a sufficiently large number of specimens to be final. Moreover, two generations of zoologists could scarcely fail to add new forms to a fauna that was published between 1845 and 1855, or to discover new points in the natural history and anatomy of these attractive mollusca. Hence the need for the present volume, and hence its matter. The illustrations are largely drawn by Alder and Hancock, and have been kept, in the long interval since they were made, in the Hancock Museum at Newcastle-on-Tyne. Sir Charles Eliot has had them reproduced and added to. His long and extensive acquaintance with the subjects and its literature in many lands has qualified him to write a text that shall worthily compare with that of the seven previous parts. The result is one upon which the author and the Ray Society may be warmly congratulated.

Few occurrences make such a pleasurable impression upon a zoologist as one's first encounter with a member of this group of animals. On turning over a stone from the heap that lies covered by laminarian fronds, a grey, slimy object disengages itself from the rich animal undergrowth, and on transference to a vessel of water, straightens out its foot, erects its sensitive "feelers," and waves its serried "cerata." The slimy blob has become a superbly coloured eolis, or an *Aegirus punctilucens,* with coloured light emanating from the sparkles on its mantle. Such a transformation is not readily forgotten, and when the attraction of nudibranchs has once been felt, it is not easy to resist the temptation to investigate so many of these creatures as can be examined in a state of nature. The search for them takes one into the rich pastures of the sea, and here they must be found only by acquaintance with the special haunts of each several kind. The sea, like the land, has its seasons of plenty and of poverty. In winter and early spring few nudibranchs are to be found in the laminarian beds, where later they will abound. A few Doris, perhaps, no two alike in colouring, and an *Eolidia papillosa,* may be found gnawing the base of a sea-anemone or winding that pink gelatinous band of eggs which is to people the water with quaint free-swimming larvæ. But as spring comes, the nudibranchs increase in number, and proceed at once with the great business of procreation. The hydroids, sponges, or alcyonium are the special resorts of Doto, Doris, and Tritonia. Others affect sea-weeds, and are scarcely to be detected in the axils of their food-plant. One kind, a glutton, is found only on the eggs of certain fish. Another eats out the soft parts of a sea-squirt, and then lies buried in the eviscerated tunic. Altogether in the British area there are more than a hundred species, a synopsis of which forms the last portion of this work.

The mode of treatment may be shortly summarised. First comes a chapter on variation and distribution. In colour particularly nudibranchs offer a considerable range of variation, in part due to food, in larger part to light-factors that have as yet not been examined. Age differences between individuals of the same species introduce another source of diversity, and the phenomena of autotomy among Eolids is a further cause of discrepancy. With regard to distribution, Sir Charles Eliot summarises a great mass of evidence in a few pages. The most salient facts are the similarity of the nudibranch faunas in the northern and southern parts of the Atlantic, the similarity of the nudibranchs in the North Atlantic and North Pacific Oceans, and the distinctness of a tropical fauna in the intermediate zone.

"It is interesting to see that the waters of the South Atlantic beyond the tropics contain forms very similar to those found in the north, if not identical with them" (p. 11).

Eolids appear to be preponderant in Arctic and Antarctic waters, Doris in tropical waters. With regard to the vexed question of nomenclature, Sir Charles takes up a position intermediate between the "lumpers," such as Alder and Hancock, and the "splitters," such as Bergh, and he has many valuable remarks on the synonymy of the more difficult species. Two interesting chapters follow on the bionomics and

development of the group and on the anatomy of Doris and of Æolidia; whilst the questions of classification, affinities, and descriptions of species occupy the latter half of the work. On these sections, the author's intimate knowledge of his subject confers a philosophic caution and breadth of treatment. Attention may be directed especially to the discussion of the relations existing between nudibranch and tectibranch mollusca (pp 89–92), and to the descriptions of fifteen species not described in the monograph. Malacologists are under a great debt to Sir Charles for this fine work, which is worthy of the classic that it supplements.

F. W. G.

WILD FLOWERS.

Wild Flowers of the British Isles. Illustrated and written by H. Isabel Adams. Revised by James E. Bagnall. Vol. ii., order xlii., Campanulaceæ to order lxxxvi., Araceæ, completing the British Wild Flowers with the exception of Water Plants and Trees. Pp. xi+199. (London: W. Heinemann, 1910.) Price 30*s.* net.

THE talented author of the volume under review has made the fatal mistake of attempting to serve two masters, and with the inevitable result. From the artistic point of view the plates are for the most part very good, and they combine accuracy of detail with beauty of arrangement. No doubt they have suffered somewhat in the process of reproduction by the three-colour process, especially as regards the green tints, but the original drawings must be excellent. An attempt has been made to produce a British flora of an up-to-date character, based on the last edition (10th) of the London catalogue, and also to produce an illustrated flora. The work before us is incomplete from both points of view.

As a flora the omission of trees, referred to on the title-page, is a great mistake, but the complete neglect of Juncaceæ, Cyperaceæ, Gramineæ, and other monocotyledonous natural orders, without a word of explanation, deprives the book of any real scientific value. "Water plants" are also said to be excepted, as well as trees, but the definition of a water plant adopted by the writer must be individual and peculiar since *Hottonia palustris, Nymphoides* (*Villarsia*) *peltatum, Lobelia Dortmanna,* and others are not only included but illustrated. It is not easy to suggest any reason for the omission of other natural orders not specifically referred to, such as Elæagnaceæ and Loranthaceæ. There can be no question that both sea buckthorn and mistletoe are "wild flowers of the British Isles"; the former might be ruled out of court as a tree, but its claim to inclusion is a strong one when the non-British *Lycium chinense* forms the subject of a well-executed drawing. The common privet, too, is scarcely a tree. Plantains also, wild flowers *par excellence* and decorative also, fail to find a place in the volume, and one is tempted to conclude that certain plants do not find favour with the writer. It is not a case apparently of the weakest going to the wall or of suffering minorities, since other natural orders with only one or two genera are to be found in their proper place.

The descriptions of the various species are on the whole well drawn up, and some interesting general information is given under each natural order. An attempt is made in some orders to make a slight key to the genera and species, but unfortunately for the unlearned student the keys are not very helpful. In the Labiatæ, for instance, the contrasted heads of the key have no logical sequence. They run as follows:—

> Corolla, 2-lipped, and usually 5-lobed.
> Stamens 4, 2 outer longer.
> Stamens 4; calyx-tube with 10–13 ribs.
> Calyx 2-lipped, closed in fruit; stamens included in upper corolla-lip.
> Corolla bell-shaped, with 4 nearly equal lobes; calyx with 5 equal teeth.

There appears to be no reason from such a key why one genus should be placed under one heading rather than under another.

Enough has been said to show that this book cannot rank as a valuable contribution to the science of botany, and it is all the more to be regretted when the excellence of the drawings is considered. Although in some of the plates there is unnecessary crowding, yet the draughtsmanship throughout is of a high order, and the plates of Convolvulus and *Tamus communis,* to mention two only, are beautiful works of art. A complete series of plant pictures of our British flora by Mrs. Adams would be of considerable value, and it is a matter for regret that so much skill and labour should have been expended on a book so pretentious and incomplete, which, with all its accuracy of drawing, unfortunately can only be regarded as a work for the drawing-room table.

SHALLOW-WATER STARFISHES.

Echinoderma of the Indian Museum. By Prof. René Koehler. Part vi., Asteroidea (ii). An Account of the Shallow-water Asteroidea. Pp. 191+xx plates. (Calcutta: Printed by order of the Trustees of the Indian Museum.) Price 20 rupees.

IN this carefully executed and copiously illustrated memoir the starfishes of the Indian littoral are for the first time regimented, from material collected, between the Persian Gulf and the Malay Peninsula, during thirty years of steady work, by the Royal Indian marine survey-ship *Investigator,* supplemented by local contributions from the recently commissioned Bengal Government Fisheries' steamer, *Golden Crown.*

Sixty-seven species are enumerated, of which twenty-eight are described as new. Among the novelties, though there is nothing very surprising, the species of Astropecten, Anthenea, Goniodiscus, Nardoa, Luidia, and Ophidiaster predominate.

Of old-established species several that were insufficiently characterised by their authors, or that have never been figured, are here re-described with infinite care, or interpreted by wonderfully lucid photographs, according to the requirements of each case, the author having taken the trouble to rivet attention on nothing less authentic than the very "types." This method of work, together with the fact that certain genera—

particularly the by no means easy genus Pentaceros—are practically revised, within set geographical limits, adds enormously to the value of this conscientious monograph.

Though the work is for the most part descriptive—almost commendably so in an age of easy speculation—the author takes pains to set all his species in their due relations. Of *Palmipes sarasini* he observes that its differences from its congeners are almost of generic value, and of Valvaster that its peculiarities are almost sufficiently exclusive to give it rank as an independent family. He also discusses the position of the irreconcilable genus Metrodira, which he has no hesitation in establishing among the Linckiidæ. Nor has he forgotten to notice the small parasitic mollusca found on species of Stellaster and Palmipes.

This is Prof. Koehler's sixth memoir of the fine collection of Echinoderms of the Indian Museum, and, as India is still *meta incognita* so far as the Echinoidea are concerned, we trust that it is not the last.

One criticism, however, may be offered of this memoir, as of its precursors of the series, namely, that it is too exclusively addressed to the specialist. Species are examined and described with acumen, but there are none of those synoptical tables, of educational value, which the student has almost a right to expect in a museum publication that treats in its entirety one large component of a fauna. If the author would crown his labours in this field by publishing synopses of the families, genera, and species of Indian Echinoderma, he would "thereby highly oblige" many to whom, though they are not experts, whatsoever passeth through the paths of the seas is of interest.

EXPERIMENTAL ELECTRICITY AND MAGNETISM.

(1) *Practical Electrical Engineering for Elementary Students: An Elementary Laboratory Course for Students of Electrical Engineering in Trade and Technical Schools.* By W. S. Ibbetson. Pp. xii+155. (London: E. and F. N. Spon, Ltd.; New York: Spon and Chamberlain, 1910.) Price 3*s*. 6*d*. net.

(2) *Practical Electricity and Magnetism: A First Year's Course.* By R. Elliott Steel. Pp. viii+175. (London: G. Bell and Sons, Ltd., 1910.) Price 2*s*.

(3) *Elementary Experimental Electricity and Magnetism.* By W. T. Clough. Pp. viii+255. (London: Methuen and Co., Ltd., 1910.) Price 2*s*. 6*d*.

THE first two books are intended to cover first-year laboratory courses, in the one case for technical students, in the other for beginners in science at a school or college. The usual differences are to be noted between them, the second being far more theoretical than the first, and also containing sections on magnetism and electrostatics, which the other does not touch.

(1) The system employed by Mr. Ibbetson is excellent, and could with advantage be adopted in any technical schools in which a similar scheme is not already in operation. It is perhaps to be regretted that no experiments with magnets are included, unless the student is intended to have taken a preliminary course in electricity and magnetism under the heading of physics.

Slight alterations in the experiments will have to be introduced in different laboratories to suit diverse conditions, as the book has evidently been written to fit the apparatus employed in one particular school. This defect shows itself most prominently in the too narrow specification of the instruments to be used in the experiments, instead of general advice to enable students to select instruments and resistances suitable in their range and capacity.

The connection diagrams are, on the whole, very good, the boldness of their drawing being a valuable feature. They could be improved, however, especially in the cases of more complicated experiments, by simplification of the drawings of instruments and switches and the avoidance of cross-overs wherever possible.

In experiment xxxv. the use of a standard resistance in connection with the calibration of a voltmeter seems quite unnecessary, and confuses the experiment with the calibration of an amperemeter.

"Shunt dynamo, separately excited," is a very contradictory term, which appears on p. 144; moreover, the experiment can be performed just as well with a generator with a low-resistance field winding.

The complete lack of any reference to the error due to the voltmeter current when measuring resistance by the ammeter-voltmeter method is a serious defect. When measuring efficiency in the photometry experiment, the connections are made so as to avoid this error, but no reason is given. On the whole, however, the experiments are detailed with the care and exactness so essential when dealing with elementary classes.

(2) Mr. Steel's book contains instructions for carrying out a great many experiments, but the language is hardly concise enough for scientific work. The use of supply mains and accumulators is avoided, which renders the book suitable for some few laboratories but unsuitable for many others. The comparative absence of diagrams of connections is a great drawback, and the few which appear are not good examples for students to copy from.

(3) Mr. Clough's book is intended to act as a theoretical text-book, as well as a practical guide in the laboratory, for students preparing for the elementary examinations in the subject.

Magnetism and statical electricity together occupy the first one hundred and fifty pages of the book, and voltaic electricity the remaining one hundred. Voltaic work is explained from a statical point of view in a method somewhat unusual at the present day.

The diagrams and illustrations are plentiful, and the type is varied so as to call into prominence the most important passages. Numerous exercises are given, chiefly drawn from recent examination papers, which should be very helpful for intending candidates.

A few omissions are noticeable, *e.g.* no reference is made to the moving-coil type of galvanometer, which is more frequently used than the suspended-magnet type.

OUR BOOK SHELF.

The Calculus for Beginners. By J. W. Mercer. Pp. xiv+440. (Cambridge: University Press.) Price 6*s.*

STUDENTS of ordinary endowment form the habit of observing things before words. The author of this work has therefore wisely begun with the notions of velocity and gradient of a curve before introducing dy/dx as the instrument for measuring them. The purely mathematical aspect of a limit is not omitted, but it is subordinated; the need for it precedes its introduction. For many purposes, and at any rate for initial study, this course is quite satisfactory; and the author will find most teachers in agreement with him in thinking it is also wise even for those who are to proceed to the more severe and formal study of the calculus. While he doubtless recognises that physicists, engineers, and chemists would benefit by finally surmounting the difficulties of the notion of a limit, he does not make it his business in this book to give the first importance to the difficulties of analysis presented by his subject.

The ground is covered slowly at first; some 250 pages are devoted to the case of x^n in all its bearings before $\sin x$, $\cos x$, a^x, $\log x$, &c., are discussed, even the rules for the differentiation of a product and quotient being postponed until the student is well on with the subject. Those who think that this is a large allowance of pages to the earlier part of the calculus should remember that the shortest account of a mathematical doctrine is not necessarily the one which occupies the fewest pages. An excellent feature of the treatment is the introduction of integration under the heading, "Given dy/dx, find y." The student cannot have it impressed upon him too soon that the determination of a function is often most easily carried out by first finding the rate of variation of the function. In his graphical work he has probably often observed this rate of variation, so that the notion has more chance of appearing *exact* than that of the limit of a sum, and he has at the same time the advantage of getting the most out of the newer ideas with which he has become acquainted. The introduction of e^x graphically is the necessary outcome of the author's whole method, and will give a conviction that seldom if ever results at first from the complete algebraic treatment.

The work, which is well supplied with diagrams, is certain to be used by many teachers, who will find it well adapted to meet the requirements of those for whom it is written.

A Text-Book of Organic Chemistry. By Prof. A. F. Holleman. Edited by Dr. A. Jamieson Walker, assisted by Owen E. Mott. Third English edition, partly rewritten. Pp. xx+599. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1910.) Price 2.50 dollars.

THE first edition of this book was reviewed in the columns of NATURE in 1903, and we were impressed with it as being a most useful addition to the books in English on organic chemistry. Since then we have recommended it to students, who have found its study both interesting and useful. Evidently the book has filled a want in the country, as a second edition was published in 1907, and now we have before us the third edition.

Considerable additions have been made in this issue owing to the advances in organic chemistry which have taken place. The chapter on proteins has, for example, been rewritten, and is now incorporated with the general scheme of the book, whereas in the first two editions the proteins were placed in the appendix. Furthermore, the translator has introduced the protein classification adopted by the Chemical Society, which, of course, is a great advantage to English readers. Another chapter which has been enlarged and completely rewritten is that on pyrrole.

In reading through the book one continually comes across small alterations, sometimes considerable alterations, where recent advances have shown the necessity for revision or additions. For the purpose of review, it is not necessary to direct attention to each alteration or addition; it is more to the point to remark that the book has been carefully revised and brought up-to-date, and that the high standard of the work has been maintained in the third edition. It is to be thoroughly recommended as putting in a succinct and readable manner the salient facts of organic chemistry. The book is not exhaustive, but the student who has carefully studied it will be in a position to read with understanding and discrimination larger works on the subject, which, without the previous knowledge obtained from this work would be beyond him.

F. M. P.

A Popular Guide to the Heavens. By Sir Robert S. Ball, F.R.S. Pp. xii+96+83 plates. (London: G. Philip and Son, Ltd., 1910.) Price 15*s.* net.

THERE appears to be little difference between the present book and the second edition, issued in 1905, and reviewed in NATURE of March 9 of that year (vol. lxxi., p. 437). The number of plates and descriptive text is the same, but a frontispiece has been added, giving reproductions of drawings of the miner's comet (1910*a*) and Halley's comet.

We must express astonishment that this "Popular Guide to the Heavens" should contain no reproductions of the remarkable photographs of solar faculæ and flocculi taken by Hale, Deslandres, and others in recent years. These pictures are among the most striking illustrations of celestial phenomena ever produced; yet no notice is taken of them in plate or text. The sun is represented by two plates, one showing a large sun-spot and the other some great prominences. We suggest that it would be far better not to illustrate solar phenomena at all than to let these two plates be considered to represent the most interesting pictures of modern solar physics.

The book contains many beautiful pictures and valuable maps, and is altogether an attractive volume, but there is no reason why people who possess the second edition should purchase the new issue with the view of finding further illustrations of astronomical progress.

Catalogue of Hardy Trees and Shrubs Growing in the Grounds of Syon House, Brentford. By A. B. Jackson. Pp. x+38. (London: West Newman and Co., 1910.)

THE unique collection of trees and shrubs in the grounds of Syon House, Brentford, the Middlesex seat of the Duke of Northumberland, has not been catalogued within the last sixty years, during which time there have been many changes, as specimens have died off and new species have been introduced. The chief interest lies in the fine old trees, some of which are the best representatives of their kind in the kingdom. Two black poplars, estimated to be 128 feet high, are the tallest, and an elm is about 9 feet shorter. More unique are a specimen of *Liquidambar styraciflua* that exceeds 91 feet, and a *Catalpa kaempferi* approximating to 58 feet in height. The collection of deciduous cypresses, *Taxodium distichum*, showing the so-called knees, are famous, and have been frequently described; some fine specimens of *Zelkova crenata* (Urticaceæ) are remarkable. The items of information consist, so far as is possible, of popular

name, family, situation in the garden, country of origin, and date of introduction; interleaved blank pages are provided for notes and additions. The author is to be complimented on the accuracy of his work.

The Essentials of Histology, Descriptive and Practical, for the Use of Students. By Prof. E. A. Schäfer, F.R.S. Eighth edition. Pp. xi+571. (London: Longsmans, Green and Co., 1910.) Price 10s. 6*d*. net.

WHEN Prof. Schäfer's "Essentials" made its first appearance some years ago it was at once recognised that here was the book which had long been wanted, and it has since then continued to occupy the foremost place in the estimation of both teachers and students. Every successive edition has kept the work fully up to date in regard to practical methods, descriptive letterpress, and last, but not least, illustrations. Any extended notice of such a well-known text-book is quite unnecessary; all one need say of the eighth edition is that it fully maintains the high standard of previous editions, and the author is to be congratulated on the continued and well-deserved popularity which it has obtained. W. D. H.

The Charm of the Road. England and Wales. By James J. Hissey. Pp. xviii+426. (London: Macmillan and Co., Ltd., 1910.) Price 10s. net.

IN his latest book, Mr. Hissey is as successful as ever in painting the charms of travel in one's own country. The journey described in the present volume was begun without a premeditated plan; the author says:—"To us the destination was a trivial detail, left to settle itself each day; the joy of the journey was the thing, therein our pleasure lay." Certainly Mr. Hissey's gossipy description of the places and scenes they met with, and the quaint experiences they were fortunate enough to have, is more than sufficient to convince the reader that the fortunate possessor of a motor-car, a pleasant companion, and plenty of leisure, can have an excellent holiday indeed in straying from one shire to another, as fancy dictates.

The excellent photographs which illustrate this interesting travel book are good testimony to Mr. Hissey's keen eye for the beautiful and picturesque.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Marine Microthermograms and the Influence of Icebergs on the Temperature of the Sea.

THE application of precise temperature measurements to the determination of the formation and disintegration of ice in the St. Lawrence River suggested to me the possibility of using very delicate electrical thermometers on shipboard to determine the proximity of icebergs. On account of the difficulty of the experiments, and the fact that well-known authorities on navigation (including Lord Kelvin) had reported that temperature measurements were likely to be uncertain, except when very close to a berg, it was some time before I could arrange for the necessary trials.

In the meantime I had devised a practical form of electrical microthermometer, which was given a thorough test on board the Canadian Government ice-breakers during the experiments made last winter to keep the river clear of ice above Quebec. So sensitive and precise did this instrument prove, that a uniform temperature gradient in the water of one-tenth of a degree per mile could be determined from the ship, approaching an ice field from open water, to an accuracy of a thousandth of a degree.

The interesting experiments of Prof. Otto Pettersson on the influence of ice on oceanic circulation, described in the *Geographical Journal* for 1904 and 1907, made it appear highly probable that the experiments I wished to try would prove successful. Dr. Pettersson showed that ice melting in salt water produced two cold currents, one of fresh water which flowed out on all sides over the surface of the sea, and one of salt water which sank down by the ordinary laws of convection. A third current of warmer sea water flowed in towards the ice, under the surface, and produced the melting of the ice.

Through the kindness of the Hon. L. P. Brodeur, Canadian Minister of Marine, passage was secured on the

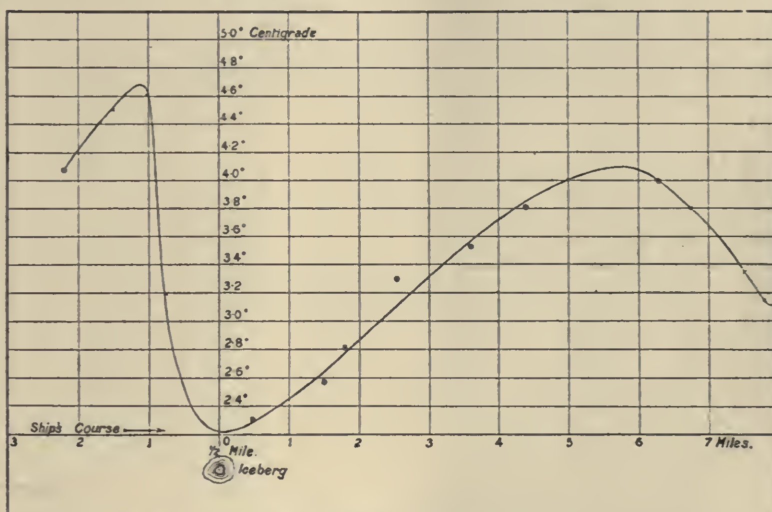

FIG. 1.—Temperature Gradient near an Iceberg.

C.G.S. *Stanley* for the trip to Hudsons Bay last July. As other duties prevented me from being absent from Montreal for so long a time, I was fortunate in being able to send Mr. L. V. King, who had so ably assisted me during the previous winter in ice studies, and who had gained great facility in using the microthermometer.

In addition to the ordinary wire bridge which we used in our river experiments, having a scale nearly 2 feet long for one degree, we adapted a Callendar recording mechanism to our needs, which gave us a scale of 1° C., equal to 8 inches. The automatic recorder could be switched on to the microthermometer at any time, and records accurate to one-hundredth of a degree obtained at any part of the temperature scale. They were obtained while the ship steamed at full speed through heavy seas, and were unaffected by the motion.

I venture to show two diagrams from the many Mr. King obtained, which illustrate the disturbing effect of ice on the temperature of the sea in summer. Fig. 1 shows the temperature gradient approaching and receding from a large iceberg passed within a half-mile from the ship in the open sea off the Labrador coast. The ship's course is shown relative to the iceberg. Fig. 2 shows a microthermogram of sea temperature traced directly from the charts. The proximity of ice is at once shown by a movement of the pen of the recorder off the scale, to return again to approximately the same position after the

iceberg is passed. In nearly every record we have there is a small rise of temperature above the surrounding sea temperature before the fall occurs, which seems characteristic of an iceberg effect.

In the light of the microthermograms we have obtained, the usual method of taking temperatures at sea seems decidedly inadequate. Thus, even if temperatures are taken over the side of a moving ship every fifteen minutes, readings are obtained at about two- to three-mile intervals, which obviously cannot be of much value in determining the temperature gradient characteristic of an iceberg. They might easily, as some of our charts show, indicate a rising rather than a falling temperature. The ordinary marine thermometer, with a degree one-eighth of an inch long, would miss entirely temperature effects made perfectly plain by the microthermometer. The persistence of a temperature gradient in the direction of a ship's course is one thing which I think can be relied on to give iceberg warnings, but when the whole temperature drop is

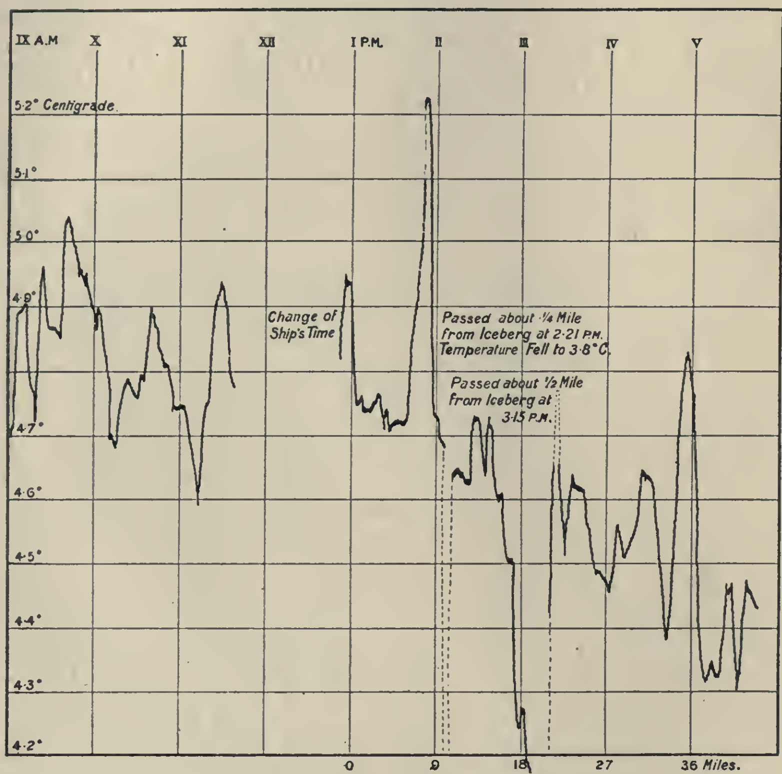

FIG. 2.—Microthermogram of the Temperature of the Sea.

fewer than two degrees in six miles it is evident that very sensitive thermometers must be used to detect it.

Besides the disturbing influence of ice, the proximity of land within a few miles produces effects of great magnitude as compared with the remarkably small variations of temperature in the open sea. In our case this was, no doubt, caused by the cold under-currents being turned up by the shoals and shore line of the Labrador coast.

For hydrographic work, the determination of current boundaries could be made with great exactness from a comparison of the temperature traces and the determination of ship's position.

The small inequalities in the temperature of the sea stand out in strong contrast to the uniform temperature of the St. Lawrence River just after the ice has moved out in the spring. These inequalities of temperature suggest at once the possibility of a vertical circulation set up by convection currents, which must be an important factor in the retention of the solar energy absorbed by the sea. It explains why our records of air and sea temperatures show no diurnal variation, except in the former case when near land. It seems to be well known to biologists that small temperature variations in the sea may be set up by the existence of marine life, and it is difficult to think of any other cause for what we have observed. It is interesting as indicating how important a part marine life probably plays in the conservation of solar energy.

H. T. BARNES.

McGill University, October 27.

Dun Coat Colour in the Horse.

MY attention has been directed to a letter in NATURE of November 24 over the signature of Prof. J. Wilson. He disputes the accuracy of certain extractions from "The General Stud Book," which originally appeared in *The Veterinary Record*, in my paper on the inheritance of dun coat-colour. Prof. Wilson also states that in the Stud Book entries there is a considerable element of doubt. This would appear to be the usual attitude of his mind in relation to data which do not exactly fall in with his own theories.

Let me first take the case of the mare Silverlocks (foaled 1725). I most emphatically deny that "the Stud Book assumes" that this mare, which is described as a chestnut on p. 1, vol. i., is identical with a mythical chestnut mare which Prof. Wilson says was foaled exactly a hundred years later. The animal to which he probably alludes was foaled in 1824, and is entered in the third volume as a "*bay colt Silverlock*," by Blacklock out of Sheba's Queen. I would direct Prof. Wilson's attention to the fact that the chestnut mare Silverlocks (1725) is the only *mare* of that name in the first four volumes of the Stud Book, and that the Stud Book entry is perfectly authentic, since it was extracted from an early Racing Calendar which describes Silverlocks as a chestnut mare by The Bald Galloway, out of a sister to Chaunter. This mare was raced for some years, and there is no room for doubt that she was the dam of the dun colt Buffcoat, foaled 1742, and of his two dun sisters, foaled in 1738 and 1739 respectively, all three being by The Godolphin Arabian (brown or bay). Does Prof. Wilson mean to imply that Lord Godolphin was so dishonourable as to run Buffcoat under a false pedigree, for that in effect is what he would have us believe? I have already directed his attention in a private letter to the circumstance that I have a portrait of Silverlocks (1725) which shows her an unmistakable chestnut, and not a dun.

In regard to the dun filly Sarah Curran (1892), by Robert Emmett (bay or brown), out of Cellulites (black), Prof. Wilson is certainly misleading, for he fails to disclose the fact that Messrs. Weatherby distinctly state in vol. xviii., p. 727, that "this mare erroneously appeared in the last volume as dead." Now, whether Prof. Wilson likes it or not, the breeder of Sarah Curran, Mr. J. T. Hartigan, returned this mare as a dun. I judge he was in a better position to form an opinion concerning her pedigree and colour than my critic, who never saw her.

Prof. Wilson says that the filly (1886) by Lord Gough (bay) out of Danseuse (brown) is described as a bay. Here again he does not state the whole truth. As a matter of fact, this filly was returned as bay when a foal, but her breeder specially altered the colour to *light dun* in vol. xix. She had then reached maturity, and was a brood mare.

I do not wish to take up your space in quibbling as

to whether *bay-dun* or *bay or dun* better describes the filly (1907) by Ash (chestnut) out of Unexpected (bay). Here, however, is another instance of reversion to dun which has come under my personal notice, viz. bay-dun hackney filly (foaled 1898), bred by the late Dr. W. Wingate Saul. She was by General Gordon, brown (gametic composition brown-chestnut); her dam, Fanny Gordon, a light yellow bay with black dorsal band. Fanny Gordon was by General Gordon out of Lancaster Fanny, dark liver-chestnut. J. B. ROBERTSON.

Lancaster.

Lower Cretaceous Angiosperms.

IN the course of my work at the British Museum on Cretaceous plants, I have examined a number of more or less perfectly petrified "woods." Such specimens have generally been classed together as "Gymnosperms," so that they have received little attention from palæobotanists. As I am undertaking an exhaustive study of the Cretaceous plants, the keeper of geology has had sections made of all the likely specimens of woods.

Among those sectioned are Nos. V. 11517, V. 5654, and V. 5452. These are of exceptional interest, because they prove to be, not Gymnosperms, but Angiosperms. One of them is further notable in having its phlœm and cortex petrified, as well as the wood; the majority of silicified woods having lost these soft tissues. The specimens were collected at different times, which minimises the chances of error in referring them to the Lower Greensand; and from geological and petrological evidence there is no reason to doubt that they are, as labelled, of Lower Greensand age (*i.e.* the Aptian of the Continent).

I hope shortly to publish a complete and illustrated account of these specimens, but I make the discovery public now in the hope of obtaining further evidence. Hitherto the floras between the Wealden and Tertiary ages in Britain have not received much attention, owing to the very scanty and imperfect nature of the fossils representing them. Nevertheless, many collectors may have laid aside "wood" from the Greensands, Gault, or Chalk, and, if so, might be willing to lend them to me for examination.

So far as I am aware, the specimens, the nature of which I have recently determined, are not only the oldest Angiosperms from the north of Europe, but are the oldest from any locality with *petrified* structure. From the succeeding Albian, Fliche described an angiospermic wood —*Laurinoxylon albiense*—which he remarked was then (1905) the earliest known petrified Angiosperm. The numerous Angiosperms described from the United States and elsewhere from the Potomac and succeeding formations are leaf impressions only.

The existence of Angiosperms in northern Europe at so early a horizon as the Aptian is a fact which will necessitate revision in some current views as to the early distribution of the most important group of plants.

Manchester University. M. C. STOPES.

The Cocos-Keeling Atoll.

As a contribution from a frank supporter of Sir John Murray's theory of the formation of the lagoons of atolls by solution, I welcome the criticism of Miss Drummond (NATURE, November 24).

I must, however, point out that the discussion does not concern the question of the power of sea water to dissolve calcium carbonate, a fact which, so far as I know, is not doubted, but deals with the more special problem of whether this power for solution is the factor which has caused the development of atoll lagoons.

She has asked me a question, and I think that she has herself given the answer to it.

Taking the case which Miss Drummond presents, and accepting all her figures, we have the following facts. Normal sea water contains 0·12 gram of calcium carbonate per litre, and will form no precipitate on standing for any length of time. Sea water that contains more than this quantity (*i.e.* 0·649 gram per litre) will deposit calcium carbonate "in the crystalline form, and the deposition may go on until the solution contains less than is normally present in sea water." . .

In this last case, the saturation of the solution, in falling from 0·649 gram per litre to less than that of normal sea water, has passed through a stage at which it is represented by the normal 0·12. Therefore, in this case, sea water containing 0·12 gram of calcium carbonate per litre will precipitate calcium carbonate, and go on precipitating it until it contains "less than is normally present in sea water." This fact therefore negatives the first statement that sea water containing 0·12 gram per litre will not precipitate. What is the factor that determines the precipitation from normal (0·12) saturation in this case when, as Miss Drummond says, sea water when allowed to stand will not precipitate? I would suggest that it is the presence in the solution of the already formed crystals of calcium carbonate—a condition which is also present "in the interstices of the massive corals in the lagoons."

F. WOOD-JONES.

Conflicting Dates of International Congresses.

AT the request of the Swedish geologists, the International Geological Congress took place this year instead of in 1909. This year was also that in which the International Zoological Congress naturally fell to be held. Since, for the convenience of university workers, these congresses are usually held at the same time of year, and since they, with their excursions, now extend over a considerable period, especially in the case of the Geological Congress, it was almost inevitable that the times of the meetings should clash. This may not affect a large number of participants, but it is rather hard on palæontologists, whose interests lie in both camps, and who, even with the aid of the aëroplane, cannot be in two places at once.

I should not trouble you with a complaint about what appeared to be inevitable this year were there not signs of the same difficulty recurring in perpetuity unless protest is at once raised. As a matter of fact, the committee of "Palæontologia Universalis," when it met at Stockholm, forwarded to the council of the congress a request that this interference should be avoided in future. That protest seems to have been without result. If so, in 1913 the palæontologist will again find himself summoned either by duty or desire to opposite quarters of the globe.

F. A. BATHER.

The Megalospheric Form of *Ammodiscus incertus*.

THE interesting discovery of the megalospheric form of the above species in some abundance in the North Pacific Ocean, as described by Mr. J. A. Cushman in Bulletin No. 71, U.S. National Museum, 1910, pp. 73–5, and noticed in NATURE of September 1, brings to mind the remarkable occurrence of the megalospheric form only (*A. tenuis*, Brady) in some dredgings off Great Barrier Island, New Zealand, which I described in the Transactions of the New Zealand Institute in 1905 (1906). Curiously, the microspheric form was there entirely absent, although Dr. H. B. Brady had previously recorded it from a neighbouring *Challenger* station, No. 169. The latter author regarded *A. tenuis* as perhaps a local variety of the better known *A. incertus*. Rhumbler suggested that the form was possibly the megalospheric stage of the species, whilst the present writer, noting a large amount of variation in the initial chamber, suggested that a microsphere might be present in forms otherwise to be regarded as *A. tenuis*, giving the diameter of the initial chamber in the New Zealand specimens as 100 μ to 50 μ. Mr. Cushman's published figure shows an approximate internal diameter of the proloculum as 250 μ, which is nearer to Brady's published figures than to the examples from the Great Barrier Island. I am now convinced that the specimens from the latter locality had abnormally small megalospheres, giving the minima of measurements so far as known.

A question here arises how to account for the remarkable abundance of *Ammodiscus incertus*, clearly of microspheric relationship, in fossiliferous strata from the Upper Silurian to the late Tertiary. With that problem as a suggestion for observant rhizopodists I conclude this note.

F. CHAPMAN.

National Museum, Melbourne, October 20.

THE PHOTOGRAPHY OF NEBULÆ.

SINCE the year 1880, when Henry Draper, of New York, achieved the first success in photographing nebulæ, namely, the great nebula in the constellation of Orion, the progress made in this branch of astronomy has been both rapid and secure. In this country Common and Isaac Roberts, in France Janssen and the brothers Henry, in Germany Max Wolf, and in the United States W. H. Pickering, Barnard, and Keeler, all have helped to obtain the high standard of excellence which prevails to-day.

Both refracting and reflecting telescopes have been rivalling each other to obtain the mastery in this particular branch, and I think that it is generally conceded to-day that the latter have won the day. The great success achieved is no doubt partly due to the important progress made in the preparation of the photographic dry plate, but a closer scrutiny of the whole situation brings into the light the peculiar skill of the man at the telescope. Isaac Roberts, for instance, had not a very large reflector to work with, one of only 20 inches aperture, yet his skill in tuning up his instrument and his very careful "following" were rewarded by the magnificent set of wonderful photographs which he was able to secure.

Again, Keeler, with the Crossley three-foot reflector, an instrument made in 1879 by Dr. Common, which only reached the United States in 1895, achieved his success only by making a very careful study of and alterations in the telescope and its accessories. While the changes he made were small, they had, as he said, "greatly increased the practical efficiency of the instrument, and therefore, small as they are, they are important." Unfortunately, Keeler died soon after he had commenced his photographic study of the nebulæ, but the handsome volume published as a tribute to his memory ("Publications of the Lick Observatory, vol. iii., 1908"), and containing splendid reproductions from his negatives, will give the reader some impression of the fineness of his work.

Beautiful as the photographs which up to the present time have been secured are, there was inherent in them some defects which it might have seemed impossible to eliminate. There is little doubt but that all these photographs must now be consigned to the second position, to be replaced by those that are the work of Prof. G. W. Ritchey, of the Mount Wilson Observatory.

Prof. Ritchey is one of the band of valuable men which Prof. George E. Hale was fortunate enough to surround himself with in the establishment of the Mount Wilson Solar Observatory. Prof. Ritchey was previously one of the staff of the Yerkes Observatory, and was in charge of the instrument shop at that observatory, and this shop was regarded of very great importance, since it alone rendered possible the construction and frequent improvement of instruments of new type or special design; provision was also made for optical work on a large scale. At the Mount Wilson Observatory the instrument shop was naturally of fundamental importance, and it was not long before the figuring and mounting of a 5-foot reflector was undertaken. This instrument was first tested visually in December of the year 1908, and the first celestial photograph was secured in the same month of that year. The instrument, mounting, dome, building, and accessories were all carried out from the plans of Prof. Ritchey, and it is with this powerful instrument of research and close attention to refinements that he has been able to make this progress in the photography of nebulæ.

In the efficient working of a reflecting telescope it is of great importance to secure as far as possible equal temperature conditions for the telescope, dome, and inside and outside air. Thus the telescope and mirror must not be allowed to be heated up during the daytime because change of temperature causes a deformation of the reflecting surface of the mirror and an alteration in the length of the telescope itself. Again, bright sunshine on the dome causes the building to become heated, and this in turn affects the telescope and mirror and produces temperature errors.

It is chiefly the elimination or practically the almost complete elimination of such temperature changes that has allowed Prof. Ritchey to secure his admirable photographs, and a brief account of the way he has achieved success will be of interest. In the first place, tests were carried on in the optical shop to determine how large a *daily* variation of temperature was permissible without seriously affecting the figure of so large and thick (19·4 cm. at edge, 17·5 cm. at centre) a mirror. By allowing the air temperature about the mirror to rise and fall uniformly for twelve hours

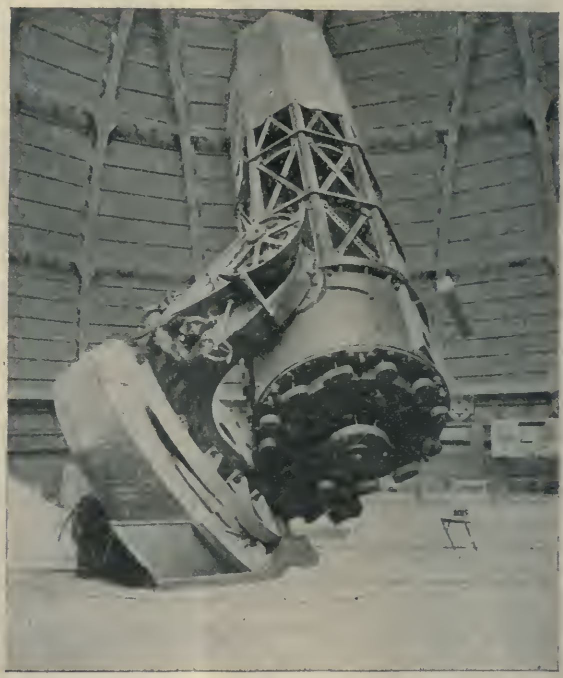

FIG. 1.—The 60-inch reflector mounting in dome.

respectively through 0° F. to 10° F., the most marked effect on the mirror was a decided disturbance of the figure on the outer zones of the surface for a distance of 3·5 or 4 inches in from the edge, these zones becoming too high as the temperature rose, and receding and even becoming too low when the temperature fell. The remaining zones were only slightly affected and the change of focal length of the mirror was small. It was finally decided that a daily variation of the large mirror of 2° F. was the maximum variation that could be permitted without perceptible injury to the sharpness of photographic star-images. When it is mentioned that the daily variation of the temperature in the unprotected dome in clear weather in the latter half of June, 1909, at Mount Wilson averaged 20° F., it will be gathered that the mirror must have altered its figure very considerably. The contraction of the steel skeleton tube was also very noticeable, for the apparent change of focal length found during the night frequently amounted to 0·04 inch.

To maintain a nearly constant temperature, Prof. Ritchey now encloses the greater part of the telescope during the daytime in a light, removable room or chamber, with insulating walls, which he calls the "canopy." The walls of this consist of four thicknesses of fine woollen blankets quilted between covers of white canvas, while the floor is of mats two inches thick, made of cheap woven hair, sewed between covers of heavy canvas. At the upper south portion of the canopy the head end of the skeleton tube projects, and this opening is closed airtight by a folding wooden cover lined with wool felt. In addition to these precautions the large mirror is protected by a short cast-iron tube, and by the airtight covers which protect its surface. Arrangements are made for moving the canopy easily and entirely out of the way of the telescope when in use, and replacing it when observing is completed. While the telescope was protected in the above manner, a sun shield was used to reduce the daily variation of the dome. This consists of gores of heavy white canvas laced to a strong framework of steel pipe. The canvas was thus retained two feet from the steel covering of the dome, due provision being made for the free circulation of the air beneath the canvas. In this way the daily variation in the dome was decreased to 10° F. in July, while the change in focus of the mirror was reduced to 0·02 inch.

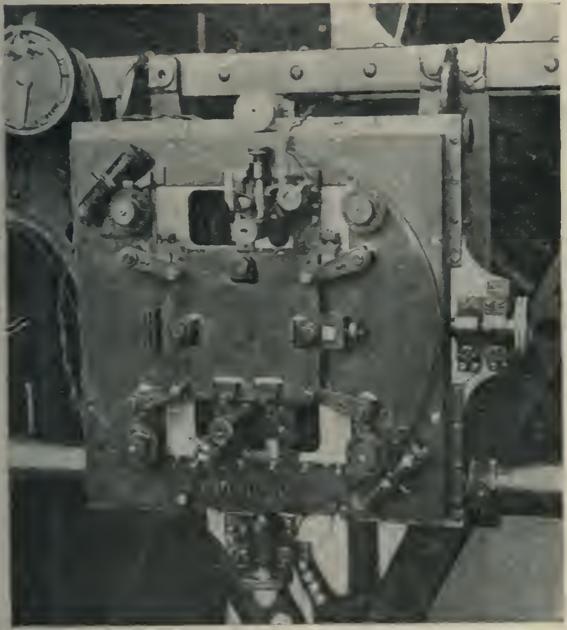

FIG. 2.—The new photographic plate carrier on the 60-inch reflector.

By the combination of shield and canopy, the inside daily variation of temperature in the latter was only 3·8° F. in August and September, and the apparent alteration of focus reduced to 0·005 inch. Prof. Ritchey proposes, in future, two improvements when he still further hopes to reduce this daily amplitude of variation, first to place in the canopy a small refrigerating apparatus with a controlling thermostat, and, second, to enclose the complete telescope in the canopy.

With these refinements in controlling temperature changes, he adopts the knife-edge method of focussing the stellar images, a most important consideration in stellar or nebular photography. By this means he is able to locate the focal plane to within 0·001 inch. With the help of his new plate-carrier, the focal plane and the plane of the film of the photographic plate can with certainty be made to agree within 0·0003 inch. While making an exposure he has occasionally to remove the plate to check the position of the focal plane of the mirror. Since the adoption of the canopy and shield he has found that re-focussing about every half-hour in the early part of the night, and about every three-quarters of an hour after 11 p.m., is sufficient for accurate working.

The efficiency of the whole instrument is such that Prof. Ritchey states:—

"All of the uncertainties which usually occur in making long exposures with very large instruments are eliminated. A plate can be exposed night after night, if desired, with the assurance that no error in focus greater than one or two-thousandths of an inch can occur, and that no rotation of field can take place without immediately being detected and corrected. Both of these conditions are absolutely necessary for the finest results with an instrument so powerful and sensitive as the 60-inch. . . . On the best of these negatives, with exposures of eleven hours, the smallest star-images are 1·03 seconds in diameter."

To ensure the finest of final products, Prof. Ritchey lastly abandons the use of rapid plates, which, as is well known, are always associated with coarseness of grain, and employs Seed "23" plates almost exclusively.

A close examination of the reproductions of some of the nebulæ which he publishes with his latest communication indicates in a striking manner the wonderful sharpness and richness in detail of his photographs. It is interesting in this respect to compare Ritchey's photograph of the spiral nebula Messier 51 Canum Venaticorum, with that of Keeler, reproduced in vol. viii. of the "Publications of the Lick Observatory" (plate 47), those of Isaac Roberts in vols. i. and ii. of his "Photographs of Stars, Star Clusters, and Nebulæ" (plates 30 and 15 respectively), and, lastly, that by Ritchey himself, taken with the 2-foot reflector of the Yerkes Observatory, and published in vol. ii. of the "Publication of the Yerkes Observatory" (plate 29).

Bearing in mind the differences in quality of the reproductions to which references above are given, the superiority of Ritchey's latest achievement is well marked.

In a more recent announcement (*Monthly Notices*, R.A.S., vol. lxx., Supplementary Number, No. 9), and dated September 17, Prof. Ritchey directs attention to very important conclusions which he is able to arrive at from his recent photographs. These are that the spiral nebulæ are not only distinguished by many sharply-marked characteristics from all other classes of nebulæ, but that the spirals themselves exhibit marked differences from each other in regard to the distribution of the nebulous stars, differences which, as he states, possibly correspond to successive stages of development.

It is in the presence of such photographs as these, and more especially those where the nebulæ are of a spiral nature, that one's attention is directed to the question of the origin of stars themselves.

"All self-luminous bodies," as Sir Norman Lockyer states in the first of his General Conclusions at the end of his work 'The Meteoritic Hypothesis,' "in the celestial spaces are composed either of swarms of meteorites or of masses of meteoritic vapour produced by heat. The heat is brought about by the condensation of meteor swarms due to gravity, the vapour being finally condensed into a solid globe."

Such a photograph as that of Messier 51 seems to represent the above words in picture form. Prof. Ritchey, in commenting on these spirals, which he has most recently photographed, says, that they all "contain great numbers of soft star-like condensations which I shall call *nebulous stars*. They are possibly stars

in process of formation. In general they lie in streams which follow the curvature of the convolutions. Together with the smooth nebulous material in which they are apparently floating, and out of which they are apparently forming, they constitute the convolutions."

While a detailed study of individual nebulæ endorses the meteoritic hypothesis regarding the formation of stars, the hypothesis itself requires the presence of a considerable quantity of self-luminous or non-luminous matter scattered throughout space. The recent advances in the photography of nebulæ have, however, very considerably altered the generally conceived notions regarding the amount of nebulous matter distributed in the heavens. After Keeler turned his attention towards photographing nebulæ, he soon found that he was able considerably to increase the number of known nebulæ with the aid of the Crossley reflector. In this research he reached two important conclusions:—

(1) "Many thousands of unrecorded nebulæ exist in the sky. A conservative estimate places the number within reach of the Crossley reflector at about 120,000. The number of nebulæ in our catalogues is but a small fraction of this." (2) "Most of these nebulæ have a spiral structure."

In the preface to the volume containing Keeler's photographs it is stated:—

"The number already discovered and catalogued did not exceed 13,000. Later observations with the Crossley reflector, with longer exposure-times and more sensitive plates, render it probable that the number of nebulæ discoverable with this powerful instrument is of the order of half a million."

While the above estimate relates to the capacity of the Crossley reflector, what number of additional nebulæ should be added when the very much greater efficiency and aperture of the Mount Wilson Observatory's reflector is taken into account? Prof. Ritchey, as has been shown above, has demonstrated the far-reaching capacity of this instrument and its enormously improved efficiency for nebular photography. Further, when the 100-inch reflector of the same observatory is brought into use, what will then be the approximate number of known nebulæ?

Again, while all these instruments can only record the existence of self-luminous matter in space, what estimate should be made for the number of regions in the sky in which matter which is not luminous is present? The only conclusion that can at present be drawn is that amount of matter distributed in space is really enormous compared to that which is generally conceded to be the case. If, as very probably is the case, this non-luminous matter is as frequently distributed as that which is luminous, then any hypothesis to explain inorganic evolution must be founded on a meteoritic basis.

The work of modern large reflecting telescopes in adding to our knowledge of the probable amount of nebulous matter in space is of very great importance, and the magnificent success of Prof. Ritchey in his latest achievement forms another opportunity for the hearty congratulations of all astronomers to be extended to him. Prof. Ritchey is to be envied, not only for working in a country where astronomy in all its branches is so well fostered, but for being one of the members of the staff of the Solar Observatory on Mount Wilson, an observatory which is so magnificently endowed. On that mountain, when it is decided that a spectroheliograph, which we in this country would consider of very large dimensions, would be capable of accomplishing better research if another of double its size were instituted, then promptly the necessary funds are forthcoming, and the instrument is taken in hand, built, and brought into use. Again, no sooner is a 60-inch mirror found to be a very great advance in celestial photography than one of 100 inches in diameter is immediately projected, and all necessary arrangements for its completion and erection are made. With such facilities for research, so incentive to those who are employed in the investigations, no wonder that work of the highest quality and importance can be turned out; for this reason this country, like many others, is being left far behind.

FIG. 3.—Spiral Nebula Messier 51 Canum Venaticorum. Photographed with the 60-inch reflector and the new plate carrier. Exposure 3h. 55m., February 7 and 8, 1910. Notice the roundness of the star images.

WILLIAM J. S. LOCKYER.

ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

THE anniversary meeting of the Royal Society was held as usual on St. Andrew's Day, November 30, when the report of the council was presented, and the president, Sir Archibald Geikie, K.C.B., delivered an address. Most of the matters mentioned in the council's report have been referred to already in the columns of NATURE, and others are of domestic, rather than of general scientific, interest. The council has decided "that the surplus annual income of the Darwin Fund, after providing for the silver medal and money gift prescribed by existing regulations, be devoted, not to the provision of scholarships or medals, but to the furtherance of biological research in the Darwinian field."

Upon the recommendation of the president and council of the society, the Government has agreed to continue its subscription to the International Association of Seismology for six years more, up to the end of March, 1916. In alluding to this decision in his address, the president took the opportunity to refer to Dr. John Milne's extensive work in modern observational seismology. "The valuable service which he has thus rendered to the study of earthquakes has been universally recognised, and there is a widespread conviction that the system of observing stations which he has created is worthy of being made a national undertaking."

It is proposed to publish a collected edition of the works of Sir William Herschel, under the editorial supervision of Dr. J. L. E. Dreyer. The cost will be shared with the Royal Astronomical Society.

A number of facts of importance relating to sleeping sickness in Uganda have been described by Sir David Bruce and his colleagues in papers presented to the society. The council reports as follows:—

Research on Tropical Diseases.

The work of the commission in Uganda has confirmed the conclusions, mentioned in the council's report of last year, that the *Glossina palpalis* is capable of conveying the infection of sleeping sickness for a much longer period than was thought to be the case at first, and that this fly may act as a carrier of other trypanosome diseases, such as those animal diseases that are produced by *Trypanosoma dimorphon*, *T. vivax*, and *T. nanum*.

One of the most important results of the last year's work of the commission is the discovery that the flies of the lake shore are still capable of transmitting the infection of sleeping sickness, although two years have now elapsed since the population was removed. The cause of this has not yet been ascertained with certainty, but further work is being done to determine, if possible, whether there is an animal reservoir for the *T. gambiense*, and especially whether cattle and antelope harbour the parasite of the disease, as laboratory experiments made at Mpumu suggest. This is a question of great importance with regard to the means to be adopted to control the malady.

The commission has not only done a great deal of work on sleeping sickness, but a number of researches on other maladies, human and animal, have also been carried out. Thus a disease affecting the natives in the province of Ankole, and known as "muhinyo," was investigated by Sir David Bruce and his colleagues, and the very interesting discovery was made that this malady was really Malta fever, and affected both men and goats in Central Africa.

In his presidential address, Sir Archibald Geikie referred to the losses by death sustained by the society during the year. These include the patron, King Edward VII.; foreign members: Alexander Agassiz, Stanislao Cannizzaro, Giovanni Schiaparelli, Robert Koch, Friedrich Wilhelm Kohlrausch, and Melchior Treub; and fellows, Sir William Huggins, Dr. Ludwig Mond, Dr. Shelford Bidwell, Sir Robert Giffen, Rev. Robert Harley, Mr. J. B. N. Hennessey, Mr. Edward Saunders, Sir Charles Todd, and Mr. C. Greville Williams.

The work of the medallists for this year was described by the president in the following words:—

COPLEY MEDAL.

The award of the Copley medal has this year been made to one of our own countrymen, who has been more than fifty years a Fellow of the Royal Society. Sir Francis Galton's life has been one of ceaseless activity in many varied departments of intellectual effort. Few of us can remember how he began as an enthusiastic explorer and geographer, "urged," as he confessed, "by an excessive fondness for a wild life," and with "the love of adventure" as his chief motive. He chose south-western Africa as the theatre of his exploration, penetrated into regions where no European foot had preceded him, and brought back with him a vivid impression of the scenery, physical geography, natural history, and ethnology of Damaraland and South Ovampoland. He embodied his observations in an interesting volume of travel published in 1853. That work showed that he was no mere hunter after game or seeker of adventure, but a shrewd and observant traveller, with his eyes open to every distinctive natural feature in the countries and their inhabitants. His experience in these African journeys led him to plan and to publish in 1854 his well-known and admirable handbook, "The Art of Travel," which, as a pioneering treatise in the practical methods of scientific exploration, has proved of inestimable service to the travellers of the last half-century.

Sir Francis at an early period of his career was led to interest himself in meteorology, which, as a science of observation, was then in its earliest infancy. With much labour and skill he constructed weather charts, and discussed meteorological statistics. His zeal and success in these studies led to his being chosen a member of the Meteorological Council at its origin, and he remained in that position until the council was superseded in 1901 by the Meteorological Office. He likewise acted as chairman of the Royal Society's Committee of Management of Kew Observatory from 1888 until 1900, when the work of this committee became merged in that of the National Physical Laboratory.

But it was not only in geography and meteorology that Sir Francis Galton manifested his versatile energies. He was much interested likewise in biological studies, especially in regard to questions of relationship and heredity. So far back as 1871 he began what has proved to be a voluminous and important series of contributions to these subjects. From his first paper, "Experiments in Pangenesis," down to his last volume on "Eugenics," his successive papers have shown a continuous development of ideas and conclusions. He was led from his early ethnological inquiries into the mental peculiarities of different races to discuss the problems of heredity genius from the fundamental postulate that "a man's natural abilities are derived by inheritance under exactly the same limitations as are the form and physical features of the whole organic world." To obtain further data for the discussion of this subject he carried out the elaborate statistical inquiries embodied in his "English Men of Science." Confident in the results of these researches, he proceeded after the manner of "the surveyor of a new country who endeavours to fix, in the first instance, as truly as he can, the position of several cardinal points." His results in this quest were given in his "Inquiries into Human Faculty and its Development," published in 1883. A further contribution was made by him in 1889, when his work on "Natural Inheritance" appeared. His subsequent papers and essays on "Eugenics" have still further stimulated inquiry into a subject of such deep interest and transcendant importance in all efforts to improve the physical and mental condition of the human race. It has seemed to the council fitting that a man who has devoted his life with unwearied enthusiasm to

the study and improvement of many departments of natural knowledge, whose career has been distinguished by the singleness and breadth of its aims and by the generosity with which he has sought to further them, should receive from the Royal Society its highest award in the Copley medal.

RUMFORD MEDAL.

The Rumford medal has been awarded to Prof. Heinrich Rubens, in recognition of the value of his researches in radiation. For many years he has been engaged in the experimental investigation of optical radiations of very long wave-length. In the course of this work he elaborated, in conjunction with Prof. E. F. Nichols, a method of isolating pencils of nearly homogeneous rays, using the fact that a non-metallic substance reflects very copiously waves of the same length as those to which it is opaque. If, then, a pencil of rays of mixed wave-lengths is reflected several times to and fro between mirrors of the same kind of substance, the rays finally emerging (the "Reststrahlen") have the wave-lengths of the kinds of light which the substance refuses to transmit. The light of other wave-lengths has been transmitted freely at each incidence, and by a sufficient number of reflections is ultimately removed from the pencil. By using different substances as reflectors, Prof. Rubens has isolated infra-red light of various wave-lengths up to as much as 96 μ, or about 0·1 of a millimetre; while, on the other hand, purely electric waves have been produced of wave-lengths as small as 2 millimetres. He has thus enormously extended our knowledge of the infra-red spectrum. Moreover, in conjunction with colleagues, he has investigated the absorbing and reflecting powers of substances for these long wave-length rays. He has shown that, for radiation of wave-length even fewer than ten times the wave-lengths in the visible spectrum, the reflecting and absorbing powers of metals and alloys are determined by their electric conductivities alone, in accordance with Maxwell's theory. It followed from Maxwell's own observations on the absorption of gold-leaf for visible light that agencies more complex than conductivity must be involved for these shorter wave-lengths.

Prof. Rubens has recently applied to the measurement of the long infra-red wave-lengths a quartz interferometer, and among other results he has found that the refractive index of water, for waves of length about 82 μ, is of the same order as for waves in the visible spectrum, while for the shortest Hertzian waves yet examined, about 2000 μ, it is as high as 9.

These examples will serve to illustrate how much Prof. Rubens has already done to bridge the gap between optical radiations and electric waves produced by direct electric agency, and how much more is to be expected from him in the investigation of the interval still remaining in which such fundamental changes of properties take place.

ROYAL MEDALS.

The awards of the two Royal medals given annually by our Patron the King have received his Majesty's approval.

One of these medals has been assigned to Prof. Frederick Orpen Bower, in recognition of the great merit of his contributions to morphological botany, of which department of science he is the acknowledged leader in Great Britain. Prof. Bower's early studies in this field (1880–2), on the genera Welwitschia and Gnetum, were marked by the discovery of the true nature of the two persistent leaves in Welwitschia. The next period of his work was given to a study of the morphology of the leaf. He developed in 1884 the idea of the phyllopodium or leaf-axis, and discussed in 1885 the apex of the leaf in Osmunda and Todea. This latter study was cognate to subsequent researches, the results of which were given in 1886 in a review of "Apospory and Allied Phenomena." This work, of much intrinsic interest, is important as having led its author to formulate the views advanced in 1890 in a memoir on "Antithetic as distinguished from Homologous Alternation [of Generation] in Plants." Another memoir, published in 1889, on "The Comparative Examination of the Meristems of Ferns as a Phylogenetic Study," prepared in the light of the then received belief that the leptosporangiate ferns are the more primitive, was followed in 1891 by a discussion of this question, in which Prof. Bower advanced morphological reasons for reversing the hitherto accepted phylogenetic order. The new conclusion has proved to be in accord with palæobotanical results, and marked another distinct step in the advancement of botanical science. During the third period of his work, 1892–1903, Prof. Bower's papers, including an important series on the spore-producing members, have resourcefully maintained the antithetic doctrine, and have afforded a striking instance of the advantage of a well-considered working hypothesis as a guide to investigation. The career of morphological research here outlined has been recently crowned by the publication (1908) of a book on "The Origin of a Land Flora," which is one of the "most important contributions to the advancement of natural knowledge, published originally in his Majesty's dominions," within the period prescribed in respect of the award of Royal medals.

The other Royal medal has been adjudged to Prof. John Joly, who is eminent in two branches of science, geology and physics. This combination of studies has proved to be reciprocally fruitful to both departments. It was from his mineralogical interests that he was led to devise the steam calorimeter, which has enriched physics with an apparatus of high refinement. The use of this method was extended by him to the direct determination of the specific heats of gases at constant volume, a measurement dealing with minute quantities of heat in circumstances quite beyond the capabilities of the usual forms of calorimeter. Among many contributions to standard physical data, which are accepted and in use, may be instanced his determination of the density of saturation of steam. His meldometer, primarily intended for determining the melting points of mineralogical and geological specimens, has been the means of providing data for use in thermometry. He has devised and applied a method of determining the change of volume of rocks and other substances on fusion, which is a datum of primary importance for cosmical theories. He has carried out a refined research, with negative results, on the possibility of minute change of mass (as distinguished from weight) accompanying chemical combination. His recent extended investigations of the occurrence of radio-active substances in materials from various strata have been utilised for fundamental geological discussions. Of other useful inventions which he has introduced, one of the best known is the translucent block photometer.

Prof. Joly has made important contributions to the subject of colour photography, and devised some years ago a three-colour system in which all three colours are present on the same plate in the form of fine parallel lines or small dots.

He has also contributed substantially to the theory of biological processes, such as the ascent of sap in vegetation. Reference may likewise be made to his suggestive memoir on the age of the earth, based upon a discussion of the chemical constitution of the ocean.

DAVY MEDAL.

The Davy medal has been assigned this year to Prof. Theodore W. Richards, as a mark of appreciation of the value of his work in the determination of the atomic weights of the elements. His researches on this subject have not been surpassed in comprehensiveness by those of any other chemist. He has himself determined the atomic weights of no fewer than fourteen elements, and many other atomic weight determinations have been made under his direction and superintendence. The accuracy of the numbers obtained is certainly much higher than that which has been attained by any previous series of researches, and it is impossible to speak in too high terms of the ingenuity, the unremitting labour, and the masterly manipulation which Prof. Richards has brought to bear on his investigations.

In addition to this work on atomic weights, Prof. Richards has made many important contributions to physical chemistry, and it is probably no exaggeration to say that he has done more to raise the standard of accuracy in physico-chemical work than any other living

chemist. Theoretical contributions to this branch of science are comprised in a series of papers on "The Possible Significance of Changing Atomic Volume," in which he suggests a relation between the energy of the atoms and their compressibilities. In order to test his hypothesis, he has made a long series of investigations on the compressibility of elements and compounds. He has determined this constant for nearly all the solid and liquid elements, and he has shown that the compressibility is a periodic function of the atomic weights. In electrochemistry Prof. Richards has made important determinations of the electro-chemical equivalent of silver, and he has supplied some of the most rigorous proofs of the universality of Faraday's law.

Darwin Medal.

To Mr. Roland Trimen, who was for many years curator of the South African Museum in Cape Town, the Darwin medal has been awarded. His official position, and the duties it involved, enabled him to do admirable work in African zoology. His name will always stand with those of Bates and Wallace in the establishment and illustration of the theory of mimicry. In addition to his researches on that subject, he has done admirable systematic work, his descriptions of insects, especially the *Lepidoptera rhopalocera*, being models of accuracy and literary style. He, furthermore, rendered the greatest assistance to Charles Darwin, especially in his work on orchids—assistance the high value of which is acknowledged in a long series of that great naturalist's published letters.

Sylvester Medal.

The medal which perpetuates the name and mathematical prowess of James Joseph Sylvester has this year been assigned to Dr. Henry Frederick Baker, in recognition of his work in the theory of functions, wherein he has shown himself to be a profound analyst. His book on the Abelian functions, published in 1897, is a classic, and probably no better guide to the analytical development of pure mathematics has appeared during the last three-quarters of a century. While basing the argument of the work on the methods of Riemann, he never loses sight of the arithmetical ideas which we owe to Kronecker, Dedekind, and Weber, or of the geometrical notions brought to light by the labours of Clebsch, Gordan, Noether, and Klein. The critical insight which was thus in evidence marked him out a few years ago as the editor of "Sylvester's Collected Papers." This work, which, with the approaching issue of the fourth and last volume, may be said to be complete, has been necessarily a difficult task, which, besides making demands upon the resources of an accomplished mathematician, has entailed no little editorial labour. Dr. Baker, by explanatory and critical observations, and by frequent ameliorations of the text, has done much to assist mathematical students. His scholarly work has resulted in a faithful record of the course of Sylvester's thought. It seems eminently fitting that the Sylvester medal should be given to one who has erected so lasting a memorial to the great mathematician.

Hughes Medal.

To Prof. John Ambrose Fleming the Hughes medal has been awarded. For thirty years he has been actively engaged in researches in experimental physics, chiefly in the technical applications of electricity. He was an early investigator of the properties of the glow lamp, and elucidated the unilateral conductivity presented in its partial vacuum between glowing carbon and adjacent metal, a phenomenon which has been linked up recently with the important subject of the specific discharges of electrons by different materials. He has published in the scientific and technical Press, and in technical text-books, many admirable experimental investigations and valuable expositions in the applications of electricity, as, for example, to electric transformers and wireless telegraphy. Of special interest and value for theory were the important results concerning the alterations in the physical properties of matter, such as the remarkable increase in the electric conductivity of metals when subjected to very low temperatures, which flowed from his early collaboration with Sir James Dewar in investigating this domain. In recent years he has taken a prominent part in the scientific development of telegraphy by free electric waves.

In the evening the fellows and their guests dined together at the Whitehall Rooms, Hotel Metropole.

ENTERIC FEVER CARRIERS.[1]

THE frequent difficulty in accounting for the source of infection of enteric fever once led to the theory that this disease could arise *de novo*, that is to say, that certain organisms in human dejecta were capable of developing, in favourable circumstances, into enteric fever organisms. It has also been maintained more recently that the specific organism of this disease was capable of living and multiplying in water and soil, for considerable periods. But the bacteriological work of the past few years has discredited both these hypotheses; and the "carrier" case of enteric fever or the mild, unrecognised case of infection generally, explain the transmission of the disease in those cases in which the disease crops up in the absence of any recognised sufferer from the disease.

A "carrier" of enteric fever is a person who, although he may be in good health, carries the infectious material in his body, from which it may pass out. He is not merely a passive transmitter of infection; he is also a breeding-ground and storehouse of these specific organisms; and it appears that not only those sick with the fever, but also healthy persons who happen to be "carriers" of the infection, offer the best explanation for the maintenance of the infection in communities.

The subject has naturally attracted much attention and led to many investigations, the results of which are to be found in numerous recent publications, and Dr. Ledingham has done a great service in preparing for publication a summary of the more important investigations that have hitherto been made of this subject. He gives the history of a large number of occurrences of enteric fever in domestic life, in institutions, and in military populations, in which the source of infection has been traced more or less convincingly to a "carrier." In many of these cases the evidence is conclusive that the infection was conveyed by food or milk. The recorded instances go to prove that the female sex is more liable to carry the infection than the male, and that of both sexes some 2 to 4 per cent. of previous sufferers may continue to harbour the germ, and become "carriers," who intermittently discharge the germ, for periods extending maybe for many years.

As Dr. Theodore Thomson, who writes an introduction to this report, states, the difficulty of dealing with "carriers" is very great indeed, having regard more particularly to the long periods during which people may harbour the infection and to the fact that it has hitherto proved very difficult to free them from the infection. The chief available measures include: all possible efforts to detect "carriers" in the community, and to endeavour to secure on the part of a "carrier" those precautions of strict personal cleanliness and of disposal of dejecta that will minimise the risk of infecting others; an endeavour must also be made to prevent such "carriers" from taking any part in the milk trade or in the preparation or handling of food.

In this interesting report, Dr. Ledingham also discusses the diagnostic methods employed in the search for "carriers" and the immunity question in "carriers." A useful bibliography is appended.

[1] Dr. J. C. G. Ledingham's Report to the Local Government Board on the Enteric Fever "Carrier"; being a Review of current knowledge on this subject. Pp. 138. (London: Wyman and Sons, 1910.) Price 1s.

NOTES.

LORD AVEBURY has been elected a corresponding member for the section of anatomy and zoology of the Paris Academy of Sciences.

WE regret to see the announcement of the death, on November 24, at sixty-four years of age, of Prof. Angelo Mosso, professor of physiology in the University of Turin.

WE learn from the *Revue scientifique* that the new astronomical observatory in the gardens of the Vatican was opened on November 17.

THE *Terra Nova*, with the members of Captain Scott's Antarctic expedition on board, left Port Chalmers on November 29 on her way south.

PROF. R. A. SAMPSON, F.R.S., professor of mathematics and astronomy in the University of Durham, has been appointed Astronomer Royal for Scotland and professor of practical astronomy in the University of Edinburgh, in succession to Mr. F. W. Dyson, F.R.S.

ON account of the General Election, the annual dinner of the Institution of Electrical Engineers (originally fixed for December 6) has been postponed to Thursday, February 2, 1911.

THE French Society of Biology has, says the *Revue scientifique*, awarded the Godard prize to Mlle. Anna Drzewina. The prize is awarded every other year for the best biological work.

THE Emperor Francis Joseph has conferred the Austrian great gold medal of science and literature upon Mr. E. Torday, the leader of the scientific expedition sent out by the British Museum to study the native tribes in the Kasai basin of the Congo.

THE *Scientific American* announces that Prof. Frank H. Bigelow, who recently resigned from the United States Weather Bureau, has joined the staff of the Argentine Meteorological Office.

WE learn from the *Times* that, owing to ill-health, Mr. Goodfellow, the leader of the British expedition to Dutch New Guinea, has been compelled to return home, and that the committee of the British Ornithologists' Union has appointed in his place Captain C. G. Rawling, who represents the Royal Geographical Society on the expedition.

THE death is announced, at fifty-three years of age, of Mr. F. Howard Collins, the author of "An Epitome of the Synthetic Philosophy of Herbert Spencer" and "Author and Printer: a Guide to Authors, Editors, Printers, Correctors of the Press, Compositors, and Typists." Mr. Collins was awarded a medal at the Franco-British Exhibition of 1908 for his "Simplified Mariner's Compass Card."

DR. HENRY WURTZ died recently at Brooklyn in his eighty-third year. At the beginning of the Civil War he was chemical examiner in the U.S. Patent Office, as well as professor of chemistry in the National Medical College at Washington. He was the author of numerous scientific treatises, and for some time editor of the New York *Gas Light Journal*. The mineral wurtzilite was named after him, and he was also the discoverer of the minerals huntilite and animikite.

A RECENT issue of *Science* gives an interesting account of the development of the Rockefeller Institute for Medical Research. The establishment of the institute is the culmination of a series of gifts, each one based on a demonstration of actual needs and on evidence of a wise use of previously available funds. The initial gift was made in 1901, when 40,000*l*. was provided to be used in a limited number of years in the form of grants to support research. In 1902 a donation of 200,000*l*. was received to cover the erection of a laboratory and the cost of current expenses for a few years. When the plans were being prepared for the future organisation of the institute, the necessity for having a hospital under the control of the institute was felt very much. Mr. Rockefeller decided to erect a hospital, and provided a further 124,000*l*. for the purpose. In 1907, while the plans of the hospital were being prepared, Mr. Rockefeller gave 520,000*l*. to be used solely for the endowment of the institute. This year the trustees of the institute assumed possession of 764,000*l*., the generous patron's latest gift. Up to the present time the work of the institute has been confined to laboratory studies of physiological and chemical aspects of diseases and to surgical and other problems that could be studied on animals. The need for the direct study of diseases under conditions that would permit accurate observations with the aid of comprehensive equipment led to the foundation of the hospital. Instead of being compelled to treat almost every kind of disease, as in a general hospital, the physicians will concentrate on a few ailments. The hospital will have physiological, chemical and biological laboratories to supplement those in the institute. The laboratories of the hospital will be devoted to investigations bearing on the diseases under treatment, while the laboratories of the institute will continue their investigations as conducted at present.

AT the last meeting of the Cotteswold Field Club Mr. L. Richardson pointed out that the so-called "stone circle" on Shurdington Hill, near Cheltenham, was really of natural origin. A slipping forward of the Upper Lias Clay was accompanied by undermining of the basal Inferior Oolite limestone, and some blocks rolling down the slope had assumed the appearance of a stone circle, which is so recorded in the Ordnance Survey. The site being under the cold shadow of a northward-facing cliff is not the position likely to have been selected for an interment.

AN interesting part of the work of the Brooklyn Institute of Arts and Sciences is the arrangement of a special museum and library for the use of children, of which an account is given in the report for 1909. The institution contains rooms devoted to exhibits of historical interest, geography, birds, insects, and similar objects. The library is provided with special literature on these subjects suitable to the needs of its students, and interest in the study of nature is excited by the issue of picture bulletins and the exhibit throughout the year of specimens of trees in bud, flowers, and fruits. The museum is said to be widely used by children in elementary schools, and it offers facilities for training of teachers, who are thus enabled to collect materials for study by their pupils. The practical system thus organised deserves the attention of school authorities in this country.

CAPTAIN A. J. N. TREMEARNE is busily engaged in unloading the stores of ethnological material which he has brought from Hausaland. He contributes to a recent number of the Journal of the Royal Society of Arts a series of folk-tales dealing with the relations of Hausa parents and children, which from these specimens seem to be far from satisfactory, these tales being devoted to the themes of unnatural parents and disobedient children. One is some-

what of the Sampson-Delilah type, in which a strong man loses his power through love of a woman. She, however, atones for this by allowing herself to be buried with his corpse, by which means she and her lover revive, and the grave becomes an iron house in which they live happily ever after.

So much discussion has arisen on the subject of eoliths that it is refreshing to find the case reviewed with good sense, knowledge of the conditions under which natural cleavage of flint may simulate the work of primitive man, and the provision of such a complete series of illustrations in the paper contributed to vol. xxi. of *L'Anthropologie* by L'Abbé H. Breuil, entitled "Sur la présence d'éolithes à la base de l'Eocene Parisien." We can only direct attention to this admirable essay, a study of which may be commended to certain enthusiasts on this side of the Channel. The same remarks apply to another contribution to the same magazine by M. G. H. Luquet, entitled "Sur les caractères des figures humaines dans l'art paléolithique," where the styles of this primitive art are illustrated by numerous well-selected sketches. The author is, on the whole, inclined to question the theory that a magical intention underlies the treatment of the sexual characteristics which are so prominent in the cave drawings.

Dr. Friederici, in describing the distribution of the sling in America (*Globus*, xcviii., p. 287), finds that it occurs practically everywhere if stones can be found. He seems to have misrepresented Peschel, who does not state (at all events in the English edition) that "slings cannot be used in tropical virgin forest," but that they "could not be used in the forest country of the Amazon," because, as he had previously stated, "no shingle is to be found." Slings could only be employed on the narrow paths, in clearings, or by rivers, but in such a country the bow is better than the sling; the spear-thrower is impracticable, as it requires so much elbow-room. He comes to the fairly obvious conclusion that the sling has been independently invented in various parts of the world.

In the Bulletin of the Johns Hopkins Hospital for November (xxi., No. 236) Dr. Harvey Cushing surveys the present status of neurological surgery, and shows how much has been accomplished during the last few years. Incidentally, Dr. Cushing deals with the value of experimentation on the lower animals. He says:—"There is no question but that a training for neurological surgery must come through laboratory experiences, and just as we are indebted to experimentation on the lower animals for almost every fact of importance which has made for the advance of this particular department, so also must we call upon them for the mere practice of hand essential to success in their clinical applications. Those who oppose the employment of animals for such purposes would leave us the only alternative of subjecting our fellow-man, as a lesser creature, to our first crude manipulations."

Ever since it was first discovered that sleeping sickness in Uganda was disseminated by the dusky tsetse-fly, *Glossina palpalis*, it has been a moot point whether or not other species of tsetse-flies are capable of transmitting *Trypanosoma gambiense*. The question is one of the greatest practical importance, since upon the answer it depends whether sleeping sickness is confined necessarily to those regions where *G. palpalis* is found, or whether it may spread over a vastly wider extent of the African continent into regions in which other species of tsetses occur. Prof. Kleine in German East Africa carried out some experiments with *G. morsitans* which led him to the conclusion that *T. gambiense* was unable to go through its development in, or be transmitted by, this species of tsetse (*vide* Sleeping Sickness Bureau Bulletin, No. 11, Appendix, and No. 18, p. 197). Recently, however, several cases of sleeping sickness have been reported from north-eastern Rhodesia and Nyasaland, from regions far south of the most southerly point at which *G. palpalis* is known to occur. It is believed that in these cases the transmitting agent is *G. morsitans*, and, if so, it is an extremely serious matter. It is to be hoped that the question will be thoroughly investigated without delay.

The seventy-fourth Bulletin of the United States National Museum consists of an account of some West Indian Echinoids, by Mr. Theodor Mortensen, of the Zoological Museum, University of Copenhagen. The memoir is a short one, extending only to thirty-one pages, but it contains a revised list of North American, Atlantic, and West Indian Echinoids, amounting to eighty-two species, which should be of great value to the systematist. The work is illustrated by seventeen plates of remarkable beauty.

As we learn from a recently published guide-book, by the curator, the exhibited series of British birds in the Hull Municipal Museum is of unusual extent and interest. It includes, for instance, a large collection made by the late Sir Henry Boynton, a second formed by the late Mr. H. J. R. Pease, and a third known as the Riley-Fortune collection. Two at least of these collections were found to supplement one another, and all three are rich in Yorkshire specimens. The guide is illustrated by reproductions from photographs of some of the groups.

Bird-marking is being carried on as energetically in the United States as in Europe, and, according to an article by Mr. L. J. Cole in the *Auk* for April, with equally satisfactory results. Open aluminium bands are now employed in place of closed rings, but these, owing to their hardness, are not altogether suitable for the purpose. Up to December 1, 1909, there were recovered 911 banded birds. Special interest attaches to a number of night-herons banded at Barnstable, Mass., of which a considerable proportion was recovered. After leaving the heronries these birds scattered in a northerly direction, this direction being largely due to the circumstance that there is no land to the south. The movement indicates, however, a tendency on the part of all young birds to disperse from the neighbourhood of the nests in which they were reared, owing to food-supplies having been rendered scarce.

The question whether bees are capable of distinguishing different colours has been much discussed, one observer maintaining that the varied hue of Alpine flowers is for the purpose of enabling bees to remain constant to a particular species of plant, so that pollination is effected to the mutual advantage of the bees and the flowers. On the other hand it has been argued that flowers might be as green as leaves without any hindrance to pollination by insects. To test the question, Mr. J. H. Lovell conducted a series of experiments with glass slides of different colours, rendered attractive by patches of honey, to see which particular kind bees would visit, a blue slide being, for instance, offered first, then a red one placed alongside, and, finally, the positions of the two exchanged. As the result of these experiments the observer states, at the conclusion of a paper in the November number of the *American Naturalist*, that "bees easily distinguish colours, whether they are artificial (paints, dyes, &c.) or natural ('chlorophyl') colours. They are more strongly in-

fluenced by a coloured slide than by one without colour. Bees which have been accustomed to visit a certain colour tend to return to it habitually—they exhibit colour-fidelity. But this habit does not become obsessional, since they quickly learn not to discriminate between colours when this is for their advantage."

IN his report on marine biology, included in the administration reports of Ceylon for 1909, Dr. A. Willey states that hopes have been entertained of rendering the southern division of the Mannar pearl-oyster fishery—more especially the so-called "Chilaw paars," which were the headquarters of the industry during the sixteenth century—once more productive. The results of recent observation tend to confirm Prof. Herdman's suggestion that most of the Mannar oysters are not bred *in situ*, but are carried by currents from the coasts of southern India—a conclusion which is of the most far-reaching importance in regard to the future of the pearl-fisheries. "Many years may elapse before anything like complete knowledge can be acquired concerning the physiology of the pearl banks. The great question which compels attention at the present juncture is that of the forced production and preservation of pearl oysters as against their natural propagation when left to themselves. It is felt that something must be done, and, from the rather misleading analogy of the edible oysters, that something can be done. And this conviction is fortified by the fact that something is being done with the same species in Japan, although it is probably a distinct local race adapted to a different environment. It still remains to be seen whether interference with the natural sequence of events will prove useful or profitable under the very special conditions that prevail in the Gulf of Mannar. It is only within the last few years that any attempt has been made to fathom the mystery by the accumulation of facts."

THE question of utilising wind power in country districts is so important that special interest attaches to the collection of statistics showing the frequency of winds of given velocities. In the *Agricultural Journal of the Cape of Good Hope* (No. 3) Dr. Sutton gives such a table for East London, and compares it with a similar table previously drawn up for Kimberley. It appears that at East London the wind is commonly too strong for the ordinary type of windmill; there is a vast amount of energy in the winds of the south-east coast of South Africa awaiting exploitation, but the mechanical difficulties appear to be great.

A NUMBER of determinations of the amount of arsenic present in soil, plants, fruits, and animals are recorded in a paper by Dr. Headden in the Proceedings of the Colorado Scientific Society, vol. ix. In the virgin soils examined no fewer than 2·5 to 5 parts per million were found, whilst the subsoils contained even more, sometimes as much as 15 parts per million. Orchard soils where arsenical sprays have long been in use may contain 10 to 28 times these quantities, and yield appreciable amounts of arsenic compounds to water. Crops grown on these soils and fruits from the trees all contained arsenic, and it was also readily detected in the urine of three persons who had eaten quantities of these fruits.

THE United States Department of Agriculture has of late been carrying out careful investigations on food and nutrition. Bulletin 227 deals with calcium, magnesium, and phosphorus in food and nutrition. It appears that a healthy man accustomed to a full, mixed diet requires for maintenance of phosphorus equilibrium about 1·5 grams of phosphorus, or nearly 3·5 grams of phosphoric acid, per diem, and the organic combinations of phosphorus seem to be best adapted for the purpose. The calcium requirement is equivalent to about 0·7 gram of calcium oxide per diem. Reference is made to the value of milk in supplying these requirements. The work has been carried out by Prof. Sherman and Messrs. Mettler and Sinclair, of the Department of Chemistry, Columbia University, and full details are given of the analytical methods and of the metabolism experiments. Circular 102 gives a list of the bulletins, &c., dealing with the subject issued by the Department.

CAPT. M. PISCICELLI contributes a well-illustrated article on Lake Bangueolo to the October *Bollettino della Società Geografica Italiana*, in the form of a letter to the secretary, dated at Abercorn, May 1, 1910. The hydrographical conditions of this great complicated maze of water, marsh and islands are described, with notes on the natives and on the fauna of the region.

MR. ELLSWORTH HUNTINGTON continues his investigations on the lines of his fascinating "Pulse of Asia." In the September number of the Bulletin of the American Geographical Society he analyses the data collected by Mr. H. J. L. Beadnell respecting the Libyan oasis of Kharga, and claims that they indicate a succession of climatical changes during the last 2500 years that are in close agreement with the hypothetical "pulsations" of climate in eastern and central Asia during the same period.

THE Liverpool Geological Society may be congratulated on the opening number of the eleventh volume of its Proceedings, which contains a spirited address by Prof. J. W. Judd, F.R.S., on "The Triumph of Evolution: a Retrospect of Fifty Years." Prof. Judd has always brought his personal knowledge of the pioneers of geology to aid him in stimulating research in newer generations. He has systematically upheld the claims of Lyell as an original observer, and as one of the masters who paved the way for the general acceptance of evolution in the natural world. In the present address the relations of Lyell and Darwin, and the final "triumph of evolution" resulting from the work of Darwin and Wallace, are pointed out with vigour and characteristic clearness. This part of the Proceedings also contains papers that maintain the high standard set by the society in the explanation of local geological features.

THE scientific investigation of the German colonial possessions in Africa proceeds steadily, and in the *Mitteilungen aus den deutschen Schutzgebieten* results are being regularly published. The last number (Heft. 3, Band 23) contains five articles dealing with German South-West Africa. One deals especially with the Auin, a Bushman tribe of the Middle Kalahari Desert, which occupy a district in the eastern boundary of the territory on the border of Bechuanaland. Their habits and customs, weapons, modes of hunting, games, and other information relating to this small tribe, which are said to number some 3000, are described and illustrated. A map on a large scale attached to the same number shows the position to the south of Kilimanjaro which has been set aside as a reserved territory for those of the Masai tribe who are on the German side of the Anglo-German boundary line. The reserve contains some 2500 square miles, and lies to the west of the Pangani River.

THE results of the magnetic observations made at the Central Meteorological Observatory of Japan during 1907 appear, and are discussed, in part ii. of the annual report now published. The observatory is situated at an altitude

of 21 metres in long. 139° 45′ E., lat. 35° 41′ N., and was rebuilt in July, 1897, great care being taken to exclude magnetic ingredients from the materials employed. The present valuable report gives a brief description of the building and apparatus, and also describes the methods employed in registering the different variations of the magnets. A number of tables give the hourly values, for the whole year, of the three elements, with remarks as to the nature of the variations, indicating storms, &c. A "severe storm" was registered during the morning of February 10, 1907, the magnets having been agitated during the preceding three days. The principal disturbances are shown on fourteen large-scale charts given at the end of the report.

THE first part of vol. ii. of the Transactions of the Royal Society of South Africa includes a paper by Dr. A. W. Roberts on a preliminary determination of the absorption of light by the earth's atmosphere. The paper is a brief statement of a single determination of the coefficient of atmospheric absorption made on the summit of one of the hills of the Winterberg Range, of an altitude of about 4000 feet. More than 500 observations were made, and it was hoped at first that these observations would yield both the coefficient of absorption and the height of the atmosphere, but a variety of solutions confirmed Dr. Roberts in the view that a more refined series of observations would be necessary before any trustworthy value of the height of the atmosphere would emerge from the equations. Dr. Roberts obtained as a final value for the coefficient of atmospheric absorption at sea-level 0·19 *m*, where *m* is the apparent magnitude of a star. The mean of the results obtained by Seidel, Langley, Pritchard, Muller, and Pickering is 0·21 *m*. Taking 0·20 *m* as a mean result, Dr. Roberts points out that this signifies that 17 per cent. of all rays that strike the atmosphere perpendicularly are absorbed by the atmosphere. On the horizon the brightness of a star is reduced so that it shines with only about one-fortieth of its zenith brightness.

PROF. EDGAR BUCKINGHAM contributes to the Bulletin of the Bureau of Standards, vi., 3, a short note on the definition of an ideal gas, embodying a brief statement of the main principles of thermodynamics associated with the definition in question.

ON February 21, 1911, the well-known firm of publishers founded by Benedikt Gotthelf Teubner will celebrate its centenary. In this connection a catalogue has been issued of recent works published by Messrs. Teubner dealing with scientific subjects, which affords a striking example of the influence which private enterprise can bring into play in the advancement of learning. Moreover, the list only deals with a small portion of the Teubner publications, separate catalogues being issued for literary and other subjects.

IN the *Rendiconto* of the Naples Academy, 5, 6 (May and June), Dr. Paolo Rossi describes observations on the double refraction induced by strain in caoutchouc. The principal conclusions appear to be that the difference of the principal indices of refraction is proportional to the tension, that the results are pretty much the same for vulcanised and unvulcanised caoutchouc, and that when the elongation is maintained constant the double refraction maintains its proportionality to the tension, even though the latter gradually decreases.

THE action of light on plants forms the subject of a note in *La Nature* for October 20 by M. H. Rousset, dealing with some recent experiments by M. Combes. The author points out that the effects of light vary according to the age and nature of the plant, a strong light favouring the development of large stores of reserve material, as in the tubers of the potato and in the beet, while a weaker light favours the growth of vegetative organs. The effect of light on the ova of trout is studied by Prof. Felice Supino in the *Rendiconti del R. Istituto Lombardo*, whose experiences tend to show that blue light is more favourable to the hatching and development of the ova than red.

IN the *Rassegna contemporanea* for October (a journal which, by the way, has during the past few months contained a number of well-written articles dealing with English national movements), Signor Gino Cucchetti publishes an article dealing, as the author claims, with a suggestion by the geologist, Venturino Sabatini, according to which a remedy for the disastrous effects of earthquakes in Messina and southern Italy should be sought in an efficient scheme of afforestation. It is pointed out that the cutting down of trees in such districts may frequently result in a loosening of the subsoil, which is largely argillaceous or sandy in character, thus giving rise to faults and lessening the resistance to the effects of seismic disturbances. The cutting down of woods receives further mention in an article by the deputy Giovanni Posadi dealing with the preservation of natural beauties, while an article by Signor Arnoldo Faustini dealing with changes that have occurred on the earth's surface in recent times, with special reference to the subsidence of the island of Bogoslaw, in Alaska, possesses collateral interest in the same connection.

THE report on the work of the Government Laboratories, Johannesburg, for the year 1908–9, has recently reached us. Whilst pointing to excellent services in the past, it gives evidence of the need for further inquiry into and control over the food and water supply of the district. The total population of the colony is about one and a quarter millions, including 300,000 persons of European descent; but only 158 samples of foodstuffs other than milk were examined during the year. This, as the analyst remarks, is very inadequate surveillance. As regards the water supply, that of Johannesburg was well looked after both chemically and bacteriologically; and that of Pretoria, where excellent water is obtainable, was also examined, though by bacteriological methods alone. But spasmodic attempts only have been made to control the condition of any of the other supplies of the colony by scientific means, and no proper systematic water survey has yet been made. Among other matters, it is noted that out of a total of 8526 samples examined, more than three thousand, mostly rats, were dealt with in connection with plague investigations.

THE contradictory results which have been obtained as to the effect of a magnetic field on the potential difference necessary to cause a discharge to pass between two electrodes in a rarefied gas are explained in a paper by Prof. Righi communicated to the Academy of Science at Bologna in May, and reproduced in the October number of *Le Radium*. The electrodes were about 2 square cm. in area and from 0·5 to 8 mm. apart, the gas having a pressure of a few tenths of a mm. of mercury. The difference of potential was provided by small storage cells, and the current transmitted measured by a galvanometer. The magnetic field in which the discharge tube was placed could be raised to 9000 units. Prof. Righi finds that the effect of the field, for strengths up to about 1000 units, is to diminish the required potential, but for greater strengths to increase it, and in the case of trans-

verse fields of still greater intensities again to diminish it. He considers these results point to the existence in the gas of neutral doublets, each consisting of a positively charged ion with a negative electron as satellite.

In an offprint from the *Atti del Reale Istituto Veneto* for 1909–10 Drs. R. Alpago and G. Silva discuss hourly observations of magnetic declination and dissipation of electric charge which they made at Padua on May 14–21. The magnetic observations agree with the more complete results from magnetographs in various parts of Europe in showing a small disturbance on the morning of May 19 about the time of the supposed passage of the earth through the tail of Halley's comet. But the coincidence might well be accidental, as magnetic conditions were disturbed for several days before and after. Electrical dissipation on May 19 was in no way outstanding. A very unusual feature throughout the observations is the absence of any decided difference between the rates of loss of positive and negative charges. For both the mean percentage loss observed per minute was 3·5, which is exceptionally high for the Elster and Geitel apparatus employed. There was a well-marked diurnal variation, again nearly the same for positive and negative charges. It showed a double oscillation. The two maxima, about 1.30 a.m. and 4 p.m., respectively, were not far from equal, and were more than double the principal minimum, which occurred about 8 a.m.

An illustrated catalogue of optical lanterns and accessory apparatus, and of an extensive series of lantern-slides to illustrate scientific and educational subjects, has been issued by Messrs. Reynolds and Branson, Ltd., of Leeds. Many of the slides may be hired as well as purchased. The catalogue shows that this firm has some 10,000 slides for sale or hire, and a list of 30,000 slides for sale only will be sent on application. In addition to slides illustrating most branches of science, we notice in the catalogue particulars of a very complete series of slides to illustrate school lessons in geography.

Messrs. W. and J. George, Ltd., of Birmingham, are issuing their latest illustrated catalogue of scientific apparatus in sections, each dealing with a specific group of science subjects. We have received sections 1–4 bound in one volume and sections 5–7 in a second. Copies of the catalogue will be sent on application to teachers and lecturers in charge of laboratories, and to other purchasers of apparatus. The lists are profusely illustrated, and so arranged that reference is easy. The information provided is thoroughly practical, and will assist the teacher greatly in the choice of instruments.

Mr. W. H. Harling, Finsbury Pavement, London, is issuing in parts the fourteenth edition of his catalogue of mathematical drawing instruments and materials. Section A, forming the first part of the full list, has reached us, and gives particulars of the drawing pens, half sets of compasses, bow compasses, spring bows, and proportional, beam, and pencil compasses which are manufactured by this firm. We have also received from Mr. Harling a specimen of the set-square guide he has just produced. It is a simple contrivance in pearwood for guiding a set-square from any edge of a drawing board or sketch block. The guide should be convenient for rapid field sketch work and useful for section lining and cross-hatching. The price of the guide is 1*s*. 6*d*.

The report of the council of the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne for 1909–10 shows that the membership has suffered a net loss of eighteen during the year, having fallen to 395. The society's work, especially in connection with the maintenance of its museum, has been helped greatly by the Crawhall bequest of 6000*l*., which has been so invested that it yields an annual income of 200*l*. Without this timely aid the position of the society would be serious, and it is difficult to see how some such exceptional source of income could have been dispensed with, for in some respects the society is not so flourishing as the council wishes to see it. An issue of the Transactions of the society has been published during the year, and the concluding part of the third volume of the new series is nearly ready. The usual series of winter lectures and summer field meetings have been held. The average attendance at the evening lectures was 85, at the children's lectures 164, and at the curator's "talks" 53.

OUR ASTRONOMICAL COLUMN.

Recent Fireballs.—There was a brilliant meteor seen on Sunday, November 20, by Mr. and Mrs. Wilson, of Cheshunt, Herts, and by Mr. C. B. Pennington, of Newark. It passed over the North Sea east of Spurn Head at heights of from 73 to 33 miles. Its motion was exceedingly slow, being about 12 miles per second.

On Friday, November 25, about 7.30, a fine meteor was seen at Weston-super-Mare by Mr. J. Hicks. He was using a telescope at the moment, but a bright light caused him to look upwards, when he saw a fireball travelling in the direction from Saturn to two degrees above Altair. Near the end of its luminous flight it broke up into a string of fragments like first-magnitude stars, and went some distance farther. The same meteor was seen at Bristol travelling from between Saturn and α Arietis through the stars of Pegasus. It threw off a brilliant train of yellow sparks, and the nucleus distributed itself into a stream of particles at the end. The height of the object seems to have been from 88 to 41 miles from Portland Bill to Launceston, and its path about 93 miles at a velocity of 23 miles per second. The radiant was at about $64° + 21°$. Another but smaller Taurid was observed on November 25 at 6.52 at normal heights above Somerset, and it moved with great slowness, the speed being about 14 miles per second.

During the progress of the eclipse on November 16, at about 12h. 24m., a splendid meteor was observed from Ireland and Scotland. It had a long and rapid flight, and left a bright streak for several minutes. According to an observer near Glasgow, the meteor was apparently as large as the moon. The descriptions prove that this fireball was a late Leonid. It passed from over a point a few miles west of Glasgow to over the sea north of the Irish coast in a direction almost east to west. The heights were about 89 to 48 miles, and the length of path 145 miles.

Saturn's Rings.—Circular No. 129 from the Kiel Centralstelle contains a telegram from M. Jonckheere, of the Hem Observatory, stating that, on several evenings, he has observed a nebulous degradation of the exterior edge of the Saturnian ring A.

Cerulli's Comet (1910*e*) identified with Faye's Short-period Comet.—In a communication to the *Astronomische Nachrichten* (No. 4456) Prof. Pickering gives the elements, and an ephemeris, calculated by Mr. Meyer Lewy, for Cerulli's comet, and points out the probable identity of this object and Faye's periodical comet; such identity was also suggested by Prof. Berberich.

Dr. Ebell, having investigated the subject, finds that the observed place on November 12 differs from the calculated place of Faye's comet by only -4s., $-4{\cdot}1'$, whilst the present apparition is the most favourable and brightest since the object was discovered by Faye, at Paris, in November, 1843; he considers the identity is assured. A later telegram Prof. Pickering gives improved elements and ephemeris by Mr. Lewy, and states that the identity with Faye's comet is confirmed.

Faye's comet has a period of 7·44 years, and was re-

discovered in 1850, 1858, 1866, 1873, 1880, 1888, and 1895, although it was missed in 1903. Its orbital eccentricity is exceptionally small, and its perihelion distance (1·7) great. It is also remarkable as being the first comet of which the periodicity was determined, by Goldschmidt, directly, by calculation, without comparison with the elements of earlier comets.

A number of observations are also published, the magnitude being generally estimated as about 10. Dr. Schiller recorded it at Bothkamp on November 10 as diffused, having a suspicion of a tail, in p.a. 300°, and a granulated nucleus of magnitude 9·8. Dr. Ristenpart, on November 11, saw no tail, but an eleventh-magnitude round nebulosity of 1′ diameter with a central condensation. Dr. Cerulli announces that he discovered the comet on a plate taken on November 8.

A System of Standard Wave-lengths.—No. 3, vol. xxxii., of the *Astrophysical Journal* contains a list of forty-nine secondary standard wave-lengths published under the auspices of the International Union for Solar Research. The increased accuracy of modern research necessitated the measurement and adoption of a standard system, and to this end three independent observers were asked to determine the wave-lengths of the forty-nine iron lines now published. From the results secured for each line a mean value has been adopted, and will in future be used in solar work; the wave-lengths range from λ 4282·408 to λ 6494·993, and wave-lengths measured in this system should be designated in future by using the symbol "I.A." The primary standard is the wave-length of the red cadmium line adopted at a previous conference.

In the same journal Prof. Kayser publishes standards of third order of wave-length on the international system, determined from the arc spectrum of iron between λλ 4118 and 6494; he intends extending the measurements to λ 7900. He finds that some of the secondary standards still contain errors of from 0·004 to 0·005 A. A comparison with Rowland's wave-lengths of the solar spectrum gives differences varying irregularly between 0·15 and 0·22 A., but by subtracting about 0·19 A. from Rowland all measurements can be reduced to the international system with sufficient accuracy. Prof. Kayser tabulates about 370 wave-lengths, and gives the intensity, the probable error, and the respective differences from Rowland and the observers who made the measurements for the secondary standards, viz. Fabry and Buisson, Eversheim, and Pfund.

The Radial Velocity of Sirius.—A most exhaustive discussion of the radial velocity of Sirius is published by Herr W. Münch in No. 4455 of the *Astronomische Nachrichten*. Herr Münch measured a large number of plates taken at Potsdam during the period 1901–10, and his thorough discussion takes up the whole of a double number of the journal. It includes, *inter alia*, the errors introduced by the measuring screw, by the different widths of the measured lines, by the possible uncertainty as to the purity and wave-lengths of some of the lines, &c. Besides several lines of yet unknown origin, he finds in the spectrum of Sirius those due to Cr, Fe, H, Mg, Ni, Sc, Ti, V, Y, and Zr, and, possibly, La and Mn.

For the mean velocity of the centre of the Sirian system referred to the sun he tabulates a series of seventeen values ranging from −8·0 (March 17, 1907) to −14·1 (April 4, 1906), the mean value being −10·3 km., with a mean probable error of ±0·4 km. Omitting the observations of 1906 and 1908, which gave abnormally large values, the mean radial velocity becomes −9·8 km., with a mean probable error of ±0·3 km.

"Annuaire du Bureau des Longitudes, 1911."—The *Annuaire* for 1911 published by the Bureau des Longitudes contains the usual astronomical tables, ephemerides, &c., and also tables relative to metrology, moneys, geography, meteorology, and statistics; this year the tables of chemical and physical data are omitted, as also are matters referring to the sundial, solar physics, and the minor planets.

The special articles, four in number, are very interesting; the first deals with the sixteenth conference of the International Geodetic Association, which was held in London, and in the second M. Bigourdan publishes a great deal of interesting information concerning the total eclipse of the sun which will take place on April 17, 1912, and will be visible in France for a few seconds.

Magnitude of Nova Sagittarii, No. 2.—A telegram from Dr. Ristenpart, Santiago, announces that on November 7 the magnitude of Nova Sagittarii (96.1910) was 9·9 (*Astronomische Nachrichten*, No. 4456).

AGRICULTURAL RESEARCH IN JAPAN.[1]

The Japanese have entered the field of agricultural investigation with characteristic energy and thoroughness, and have shown a lively appreciation of the fact, not always realised elsewhere, that the principles underlying an agricultural problem must first be studied before the problem itself can be solved. Some of the special features of Japanese agriculture present highly important problems, the development of which will be awaited with much interest.

The present volume of the Journal of the College of Agriculture contains, in the two parts already published, four papers, of which three deal with silkworm problems. Mr. K. Toyama reports studies on the red worms occasionally appearing among the progeny of the normal black worms, and hitherto regarded in a general way as sports. In 1905 he obtained some red worms, and studied their behaviour on crossing. The results showed that the phenomena are really Mendelian, black being dominant over red; the red worms uniformly yielded red offspring, while the matings of the blacks resulted in the production of one red to three blacks. Prof. C. Sasaki deals with jaundice of the silkworm, a disease prevalent in all silkworm countries, and frequently found in Japan. The worms lose their appetite, weaken, and finally die; the skin loses its firmness and becomes soft and weak, while polyhedral bodies appear in the blood and various tissues. Evidence is adduced that the disease is caused by a streptothrix found in the blood of affected worms. The polyhedral bodies may, however, arise from other causes such as a small dose of formalin, interruption of respiration, or attacks of maggots, and are probably to be ascribed to the degeneration of the contents of the nucleus. The same author has also solved an interesting problem that has hitherto been overlooked. Silk fishing lines, commonly known as "Tegusu," are largely employed by the Japanese fishermen, but no one has up to the present found out any more about their origin than that they are imported from southern China. The Chinese writers say that some wild silkworms found in Yōkō on the leaves of camphor trees and Foushu (*Liquidambar formosana*) are the source. In April, when the worms are mature, they are dipped in vinegar, and then filaments 7 or 8 feet long and golden-yellow in colour are taken from their bodies. Prof. Sasaki made a journey in southern China, found the worm, and determined it as the larva of *Saturnia pyretorum*, Westwood. He has also introduced it into Formosa.

Mr. S. Kusano has a paper on chemotactic and similar reactions of the swarm spores of myxomycetes, Æthalium, Stemonitis and Comatricha being investigated. In general, these organisms feed mostly on rotten wood or leaves, and there is evidence that they can digest bacteria. It appears also that they can themselves be devoured by infusoria. Wood attacked by them was found to be acid. The swarm spores showed marked chemotaxis, being attracted by acids, repelled by alkalis, and unaffected by neutral, non-poisonous substances. A consideration of the phenomena from the dissociation hypothesis indicates that the H- and OH-ions are in all cases the stimulating components, the OH being much the more effective, and active even at a dilution of N/10,000. The attraction of the H-ion reaches a maximum at N/600; in higher concentration the acid repels and injures the organism. H-ions act beneficially in several ways; they promote germination of the spores, and then attract them to the place where food material occurs. An interesting physiological point was noticed. The spores germinate much more readily in contact with moist air than when thrown on to water; in the latter case they do not appear to be wetted very quickly.

1 Journal of the College of Agriculture, Imperial University of Tokyo, vol. ii., Nos. 1 and 2.

STOCKHOLM TO SPITSBERGEN: THE GEOLOGISTS' PILGRIMAGE.

WE geologists who were privileged to take part in the journey to Spitsbergen before the meeting of the Geological Congress in Stockholm had good reason to count ourselves fortunate. Perfect weather, genial companionship, comfortable surroundings, admirable organisation and guidance, and a route through the strongholds of Thor of the Hammer, in which intense scientific interest was constantly united with entrancing beauty of scene—surely the combination would have roused enthusiasm among much more stolid folk than the impressionable race of hammerers!

We started by special train from Stockholm, about seventy strong, an agglomerate of fifteen nationalities, on the evening of July 25, and at once left behind us the broken weather that has encircled Western Europe this summer, entering a northern region of brightness and calm in which we continued until our return. Those of us who were in Stockholm the previous day had been called together to see a fine exhibition illustrative of Spitsbergen geology, temporarily shown in rooms attached to the museum of the Swedish Geological Survey, and to hear lucid demonstrations on the exhibits by Prof. A. G. Nathorst and by the Director of our excursion, Prof. G. De Geer. Here we had already an opportunity to begin or to renew friendships that were cemented during the journey. Owing to the care and forethought with which every detail of the expedition had been planned, our start was made promptly, and we settled without confusion into our allotted places.

The night's train journey brought us to Ragunda in Ångermanland, where our first halt was made. During four hours of the morning we visited sections splendidly illustrating the evidence from which Prof. De Geer has worked out the chronology of post-Glacial time in Sweden. By a catastrophe in 1795, the great lake of Ragunda was suddenly drained and its bed laid bare; and the ravines subsequently eroded through its sediments now reveal the whole succession deposited since the melting of the Glacial ice-sheet. In these sediments Prof. De Geer recognises and counts the annual bands of the "seasonal clays," much as one may count the annual bands in a tree trunk. By the extension of the same method over various other parts of the country, he has attained results by which the recession of the ice-sheet and all its incidents may be actually dated, as he showed us later in field demonstrations near Stockholm during the sitting of the congress.

Northward again for the rest of the day and through a night of twilight, during which the Arctic circle was crossed, our train brought us to breakfast on July 27 at the bright town of Kiruna, which has newly sprung up in the Lapland wilderness under the famous mountain of iron ore. Here we remained until the afternoon, visiting the great iron quarries under the guidance of Director Hj. Lundbohm, who instructed us by a preliminary address in the geology of the district and the history of its rapid development. After a banquet to which we were invited by the mining company we took train again at 4 p.m., and ran shortly into view of the beautiful Lake Torneträsk, in a region of powerful overthrust faults and of Glacial lake-shores. Making several short halts in this wild country to examine points of especial interest within easy reach of the railway, under the guidance of Dr. O. Sjögren, we reached Abisko in the evening. Here our train remained for the night, affording us opportunity to appreciate the picturesque surroundings of Abiskojokk, now a much visited tourist resort.

On the morning of July 28 the Norwegian frontier was reached at 11 a.m. Thereafter followed a marvellous descent to the coast, along the rim of a great fiord the blue waters of which shone gloriously in the depths below us. At Narvik, our port of embarkation, we were shown the methods of treating the iron ore from Kiruna and the facilities afforded for its shipment, being thereby still further impressed with the enterprise which has been shown in the development of this great Swedish mining industry.

Our ship was the *Æolus*, Captain S. de Klinteberg, a comfortable Stockholm passenger boat of 870 tons register. Sailing from Narvik at 5 p.m., we were held up for a few hours of the night by fog in the narrow passages leading northward from the Ofoten Fiord; but this was our only delay in the charming voyage to Tromsö, which was reached next evening.

There had been rumours of unusual ice conditions in the Spitsbergen seas before we left Stockholm, and at Tromsö these rumours were partly confirmed. Our Director, therefore, learning that a French ship was due to arrive next day from the north, decided to await her coming in order to gain definite information. So we spent a calm, sunny day pleasantly at Tromsö, first visiting the museum with its excellent collection of Arctic animals and birds, and afterwards crossing to the mainland to see the Lapp summer camp or to climb the nearer mountains. Meantime the *Ile de France* had arrived, and reported that while floe-ice from Barents Sea had drifted in quantity round the south and south-west coast of Spitsbergen, the inner fiords of the island were free, so that the only difficulty was to obtain access to them, for which purpose it might be necessary to go far to the westward. With this intelligence we steamed ahead again on the evening of July 30.

As we passed northward in the shadow of the fiords a red glow of wonderful brilliancy shone on all the higher peaks and glaciers, and never faded; until, at midnight, as we passed out into the open ocean under the majestic Fugle Rock, we saw the disc of the sun just cut by the sea-line; from which it rose with seeming effort, like a heavy seabird, as night grew into morning. It was thus that most of us gained the midnight sun for the first time, not to lose it again until our approach to Norway in returning.

During the last day of July we pounded northward under a cloudy sky, with a touch of ice in the air; but in the evening we ran into sunshine again, and there, ahead of us, lay Bear Island miraged on the horizon. This was indeed good fortune, for in his eleven previous voyages past the island our Director had seen it only twice, so frequent are fogs in these seas. Our course was altered that we might run in under its eastern face. The placid sea around us was furrowed by its myriad sea-fowl, and from 11 p.m. until 2 a.m. we coasted its lonely cliffs and sea-stacks closely enough to distinguish the main features of their geological structure, and to catch glimpses of its desolate interior with all features accentuated by the light and shade of the low sun.

In its stratigraphy Bear Island is akin to Spitsbergen, though with a more restricted range of formations. To all geologists these far northern islands are of great interest, but peculiarly so to the geologists of Scandinavia, inasmuch as they contain a great sequence of the later Palæozoic, Mesozoic, and Tertiary sediments which are lacking within the Scandinavian 'shield.' To the Swedish explorers, and especially to Prof. J. G. Andersson, we owe most of our knowledge of the geology of Bear Island. At its southern extremity is a ridge of crushed and altered 'Heklahoek' rocks, which include fossiliferous Lower Silurian limestones. The rest of the land is built up of Devonian, Carboniferous, and marine Triassic strata, all in some parts very fossiliferous, and with coal seams in the Devonian. The sequence is interrupted by strong unconformities and broken by faults, some of which we could see plainly from our steamer.

Now it became difficult to chop up the Arctic day into conventional night and morning, and we counted by events—particularly by meal-times, for we were a hungry crew—rather than by the clock. Not many hours after sinking Bear Island in the southward, on August 1, we began to meet floe-ice; which soon thickened, so that we had to slow down and eventually to turn southward and westward for more open water. Again and again during the day was this experience repeated, a chilly ice-blink always paling the hazy sky to the north and east as we threaded our zigzag course amid the floes, on which inquisitive seals shifted uneasily, doubtful whether to regard us as dangerous or not. Usually at this season the voyage to Spitsbergen lies entirely in open water; but most of us were glad of the chance which gave us this touch of the true Arctic colour. Still, to the anxious captain of our ship the prospect must have been decidedly less enjoyable. Thus we steamed cautiously all day and all night among the floes or along the broad water-lanes between the great white streaks drawn out by the north-flowing

current, until we had been shouldered off 70 or 80 miles to the westward of Spitsbergen. On August 2, however, we got an easterly course, picking our way across the ice-streams where they were thinnest, and by evening the lead showed that we were approaching land. So we lay to, in a light haze, to await clear weather.

Soon, very gently, the haze thinned away; the northern sun shimmered again over the smooth olive sea, burnishing the floes into silver; and then, gradually, an exquisite panorama of peaks and glaciers was unveiled in front of us, lengthening northward and southward into a far perspective, and we knew that this was Spits-bergen, and worthy of its name. Due north of us rose the angular ridges of Prince Charles Foreland, and right ahead lay the gap of our haven, Ice Fiord; so we moved quietly forward, through a scene of dreamy splendour, to our anchorage after midnight in Safe Bay. Surely never was there a more impressive revelation of this silent land!

From this time onward our days were busy days, thronged with scientific interests and impressions that shifted all too rapidly. Within the great Ice Fiord, which runs for 60 miles eastward, crossing the strike of the rocks and almost bisecting the island, we found open water, and our ship was able to pass into all its branches without impediment. During the ensuing week we penetrated most of its recesses, landing at the best points for investigating its several formations, and gaining a clear idea of their structures from the barren craggy outcrops that rose high above all the waterways. (See Fig. 1.)

Though complex in detail, the geology of central Spitsbergen is simple in its main outlines. Earth-movements of intensity, repeated at intervals down to Tertiary times, have ridged up the western margin of the island, bringing to light the oldest rocks and crumpling them along with the newer formations. These earth-waves, with their faults, folds and overthrusts, subside eastward, leaving a high plateau of regular stratigraphy and gentle dips, which is sharply trenched by the branching fiord and its tributary valleys. On the north side of the fiord most of the valleys contain glaciers which reach the sea; but on the south side, owing to difference of aspect and other causes, the land-valleys are often empty nearly to their heads.

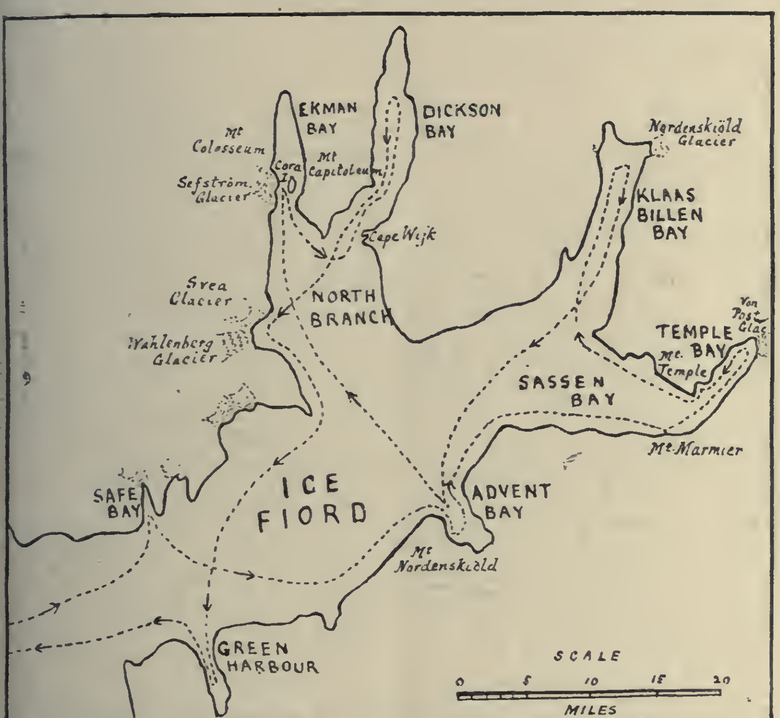

FIG. 1.—Index-map of Ice Fiord, Spitsbergen. The course of the ss. *Æolus* is shown approximately by the dotted line.

The high jagged outer ridge, at the entrance to Ice Fiord, consists of crumpled Heklahoek rocks, succeeded eastward in the next ridges by sharply folded and broken Carboniferous strata. But in the interior, the long northern branches of the fiord reveal a great mass of red Devonian rocks, very similar to our British Devonian, upon which the Carboniferous strata rest with strong unconformity and overlap. In upward succession, the Carboniferous limestones and cherts are followed by a belt of sandstones and shales, to which, on the somewhat scanty fossil evidence, a Permian age is assigned; and above these come the Triassic strata, chiefly shales or clays, with thin limestones, sandstones, and phosphate-bands, often rich in well-preserved marine fossils. The outcrops of the three last-mentioned formations are narrowed to strips in the outer folded belt, but expand into wide tracts around the interior fiord. Then follow thick masses of the Jurassic and Tertiary sediments, for the most part gently dipping and in apparent, but unreal, conformity, which build up the high picturesque plateaus on the south side of the inner fiord. These consist mainly of sandstones and shales of fresh-water or estuarine origin, but with occasional bands containing marine fossils. Both formations yield abundant well-developed plant-remains, in striking contrast with the present diminutive Arctic flora; and both include coal-seams, at least one of which, in the Tertiary rocks, is likely to be of economic consequence.

To resume the recital of our doings in this land. We were astir early on the morning of August 3, anxious to take our first steps in Spitsbergen, and before breakfast many of us were ashore among the mixture of rocks, moraines, glaciers and raised beaches that forms the west shore of Safe Bay. Leaving this anchorage at breakfast time, our ship went east across Ice Fiord and ran close in under the bold precipices of Jurassic and Tertiary rocks bounding the plateau around Mount Nordenskiöld, until Advent Bay was reached, before noon. This has recently become a place of permanent habitation—the only one in the ownerless land. Most of us were surprised at the display of engineering activity in such a remote corner, brought about by American enterprise in the development of a mine in the Tertiary coal. A shipping wharf has been erected, to which the coal is brought from the mine high up on the hill-side by skips travelling overhead on a cable. At the mine, which we visited later, a seam of good quality, 4 feet thick, is worked by means of an adit. It was singular to see the walls of the workings all thickly encrusted with a sparkling layer of hoar-frost from the condensation of moisture on rock-surfaces that are permanently below freezing point. A pure white coal-mine!

For the afternoon in Advent Bay we divided into two parties. Those who wished to study the Jurassic plant-beds crossed with the ship to the north-east side of the inlet under the guidance of our Director. The rest of us landed at the wharf and went inland towards Mt. Nordenskiöld, led by Mr. B. Högbom, who had been already for some weeks in the island on geological work under Prof. De Geer's instructions, and who here awaited us. With him we went to the glacier-filled head of the valley south of the coal-mine and ascended the plateau on the westward to an upper moraine where Tertiary plant-fossils occurred in profusion. On this moraine, at an elevation of about 1500 feet, most of us were content to stay, basking in the sunshine and enjoying the glorious view over fiords, plateaus, and snow-fields; but certain of the more energetic elder members of our party continued upward

over the snow to the very summit of Mt. Nordenskiöld (3460 feet), not reaching Advent Bay again until near midnight. The plateau which we traversed in returning to the ship was tesselated in places with fine examples of the singular "gardens" due to soil-creep—round or polygonal patches of clayey soil, up to 15 feet in diameter, bordered by slabs of stone, often on edge—which are remarkable in the Spitsbergen tundras at all levels, as in those of other Arctic lands.

Leaving Advent Bay at noon on August 4, our course was shaped eastward under the cliffs to Sassen Bay, where we made a short landing near Mt. Marmier to collect the abundant Triassic fossils and to examine the diabase which is here intruded conspicuously in sheets among the sediments. It was instructive to see how the shaly Trias, very like our Lias in composition, was creeping down the slopes in big partly frozen mud-flows, mixed with ice and with blocks of diabase, providing a mass ready to be worked up by any advancing glacier into the semblance of our darker boulder-clays. This, indeed, is the particular value of the Spitsbergen phenomena to the English glacialist, that the country rocks are analogous in structure and texture to those of England, and are rarely of the hard type prevalent in nearly all other accessible regions of present-day glaciation.

Crossing Sassen Bay, we landed our palæontologists at Cape Bjona, under the fluted cliffs of Mt. Temple, for the collection of Carboniferous fossils from the inexhaustible stores of the limestones. The glacialists then went on with the ship to the head of Temple Bay, where the Von Post Glacier comes down to the sea with a front of ice-cliffs three miles broad. This glacier is now in retreat, and lateral moraines of its former extension line the fiord on both sides for a distance of more than a mile from the present front. Ice-falls from the glacier into the sea cause waves that have carved out cliffs 30 or 40 feet high in places, clearly revealing the composition of the moraines. These cliffs were strikingly similar to those of some English boulder-clays; indeed, but for the gleam of the neighbouring ice, one might have imagined oneself under a sea-cliff of north-east Yorkshire. The red loamy clay of the sections was studded, not too abundantly, with well-striated boulders of igneous and metamorphic rocks (from some unknown source beneath the glacier) along with others, more numerous, of grey and red sandstones, conglomerate, chert, Carboniferous limestone, and other sedimentary rocks. Both moraines formed broad hummocky ridges, with troughs of lower ground behind them.

A party of five German explorers, under the leadership of Lieut. W. Filchner, who were intent upon a journey into the interior of Spitsbergen, had been with us up to this point, interesting us greatly by the preparation of their outfit during the voyage. Now, with a heartening cheer, we left them to begin their adventures, our ship returning in the quiet evening sunlight for the night's anchorage at Bjona Harbour, where the impatient palæontologists hungrily declared that we were trying to starve them into glacialism!

Next day we coasted eastward to Klaas Billen Bay, and then northward up this deep inlet nearly to its head. A new phase in the stratigraphy of the island was here most instructively displayed in its bare brightly tinted slopes. Red Devonian strata rose up in strong force on its western side until unconformably overlain by the "Culm," which is believed to be of Lower Carboniferous age, while the limestones and cherts of the Upper Carboniferous rested in still bolder unconformity on both. A great fault cuts out the Devonian at the head of the bay; and east of it the Carboniferous rocks are known to rest directly upon bosses of an ancient complex group assigned to the Archæan, which we had not time to reach. Under the instruction of our leader these complicated features were made plain to us from the ship, and we realised how great was our advantage in gaining so comfortably in an hour the knowledge that would have cost many laborious days to gather without such guidance. Most of the day was spent on shore at the western side of the fiord; then, after a late dinner on the ship, we went to land again at 10 p.m. on the eastern arm, for a midnight stroll to the Nordenskiöld Glacier, which breaks off with a sea-front of three miles in water reaching nearly 500 feet in depth. Under an overcast sky, which intensified the cold blueness of the ice, we crossed the tesselated tundra with its shelly terraces of raised beach to the southern moraine of the glacier, and saw how the grey shelly mud had been incorporated with the moraine. This was our coldest night, with no sun; but we were fortified by a camp-fire on the beach, and hot coffee, before returning to the *Æolus* at 2 a.m.

An incident of navigation had rendered it necessary that our ship should return to Advent Bay for a further supply of coal, so now she went southward across Ice Fiord to the coaling wharf, and lay there during August 6. Here, for the day, our party broke up into independent groups, some climbing the high plateaus, others going up the coalmine valley to the glaciers, and the palæontologists working assiduously along the Jurassic and Tertiary outcrops on the slopes above the bay. Next morning we left Advent Bay again for the North Branch of Ice Fiord; passing from cloud and breeze into bright still sunlight, with that local incidence of weather which appears to be characteristic of Spitsbergen, for all day we could see the cloud-banks pouring in like great glaciers from the ocean and welling up against the southern shore of the fiord.

Entering Ekman Bay, we passed along under the ice-cliffs of the Sefström Glacier, and anchored at a spot which quite recently was beneath the glacier. Above us, on opposite sides of the bay, rose the exquisitely fretted edges of Mt. Colosseum (1960 feet) and Mt. Capitolium (2790 feet), built up of nearly level Carboniferous rocks in tier after tier of belted crags, separated by high-pitched slopes and notched with amazing regularity by gullies and talus-cones (Fig. 2). We had seen similar features again and again during previous days, but here the sculpturing attained its greatest beauty, and the rhythm of light and shadow under the low sun gave a well-nigh perfect impression of architectural design. It was just the typical sculpturing of an arid climate, reminding us of scenes in the 'Bad Lands' and cañons of western America. In Spitsbergen, also, there is not sufficient precipitation to maintain permanent streams except those that have their source in melting snow and ice, so that the cones of frost-riven talus everywhere accumulate on the bare slopes above the over-deepened main valleys.

As for the Sefström Glacier, it afforded us a series of lessons of surpassing interest. When first mapped by Prof. De Geer in 1882, the sea-front of this glacier lay two or three miles back within its side-valley; and was flanked on both sides by fluvio-glacial outwash plains. Between that time and 1896, when it was again examined by our Director, it had advanced about four miles, burying the outwash plains, filling its valley up to the mountain slopes, and bulging out into Ekman Bay in a broad lobe that reached across to Cora Island, hardly a mile from the opposite shore of the bay. But its spurt was over; already in 1896 it was sinking back; and when visited in 1908, though its detached snout still hung grounded on Cora Island amid huge masses of morainic material, the main front had so far receded that there was again a sea-passage between it and the island, and a narrow strait, with ice-cliffs to right and left, between the new front and the detached portion affixed to the island. Since then there has been further recession, so that we found a wider passage; but a remnant of the melting snout still shone up conspicuously amid the red moraine on Cora Island.

We spent most of the day on the island, and I know that there was at least one glacialist of the party who felt that the time of the whole journey would have been well spent for the sake of this day alone! In its original condition Cora Island was a low spit about two miles long and half a mile or more wide, composed of Carboniferous limestone partly covered with raised beach; but it has been increased to more than twice its size by the moraine banked upon its western side during its invasion by the glacier. This moraine, which for the greater part must have been actually under the ice at its maximum, has been thrown in a tumultuous succession of ridges and hollows across the flank of the island, forming a curved belt about three miles long, nearly half a mile wide at its broadest, rising in places to 50 or 60 feet above sea-level, and ending sharply, where it touches the original island,

against the lower bare ground, with hardly any 'outwash' (see Fig. 3). It consists almost entirely of streaky red clay containing a few scratched boulders, and crowded with marine shells, some broken, but mostly perfect and the bivalves united. The clay has evidently been derived in the first place from the red Devonian rocks into which the fiord is cut; but its more immediate origin was the neighbouring sea-bottom, which has undoubtedly been dragged up in some way by the glacier in its advance. The existing remnant of the glacier was seen to be curiously entangled among the clay; and the presence of smaller masses of ice buried under the moraine was indicated by the crater-like hollows of subsidence by which its surface was pitted.

But the story of Cora Island is too long for our space—we must leave it regretfully, in the same mood that we left it on the late evening of August 7, to hasten back to our ship. On August 8 the *Æolus* carefully threaded the

different temperament; the Svea, smooth, worn, and retiring; the Wahlenberg, known to have been recently aroused into activity, and jagged, fissured, and tumbling in the rapidity of its advance. On this coast, also, our Director pointed out to us the crumpled structure of the rocky ridges separating the glacier-basins—huge wrinkles on the fringe of the western belt of disturbance. Crossing Ice Fiord once more, we found anchorage for the night in Green Bay, but not too near the malodorous whaling station, where the carcases of a dozen unshapely monsters awaited dismemberment.

On the morning of August 8 we landed on the west shore of Green Bay, and went inland up a transverse valley which cuts the mountainous ridge and very clearly reveals its structure—a steeply dipping succession of Carboniferous, Permian and Trias, with Jurassic on the shores of the bay, and Tertiary, comparatively undisturbed, above the eastern side. Mist, with a splutter of rain, hung around

FIG. 2.—Mount Capitolium (2790 feet), Ekman Bay. Carboniferous rocks (with underlying Devonian concealed by talus), showing fretted form developed by weathering.

inner recesses of Dickson Bay, where her farthest north, 78° 50′, was reached, and where the glowing redness of the Devonian rocks—in the distance like heather in bloom—gave warmth to the Arctic wilderness. Many of us, however, chose the alternative of a landing under Cape Wijk, at the entrance to the fiord, and a long climb up the shaly slopes of Permian and richly fossiliferous Trias to the plateau at about 2000 feet, formed by an intrusive sill of diabase. There, in bright sunshine, we gained a view from which not all the promised reptiles of the Trias could drag us—fiords, glaciers, and valley-trenches everywhere around; away in the north-east, snowfields and peaks above the head of Wijde Bay; and our ship a speck on the blue floor of the nearer recess. Nevertheless, it would be a desolate land to be alone in with no such speck!

That same evening, in going southward, we steamed close in under the ice-cliffs of the Svea and Wahlenberg glaciers—contiguous neighbours, but at present of very

the peaks all day, but the valley was dry. Later, a flying visit was made to the whaling station by those who could face the ordeal; and in this manner was our programme for Ice Fiord brought to its appointed end. As our ship swung westward into the floes at the mouth of the fiord the evening sunlight glittered on the land, just as it had done at our approaching; so it chanced that our last view of Spitsbergen was like our first.

It had been planned that we should visit Hornsund next day in returning southward. But the ice-floes drove us westward even farther than before, and there would have been much risk in pushing landward through them again. Our journey to the lonely island was done. So, after a few hours of devious sailing, we emerged from the tangle into the open ocean, and there rolled uncomfortably southward under a cold thick sky for the next two days, gaining the welcome shelter of the Norwegian coast on the morning of August 12. It was on the previous night that we had reached into sunset again.

Being now a few hours ahead of time, our captain took us up the lovely Lyngen Fiord, in glorious weather, with a sprinkle of new snow on all the peaks. Thus were we reconciled to the loss of Hornsund. And at Tromsö in the afternoon we returned to the world of telegrams, letters and newspapers.

Of the after-voyage through the fiords to Trondhjem it is enough to say that the weather remained perfect; and that Dr. Hans Reusch, the Director of the Norwegian Survey, was of our company, so that we missed nothing that could be learnt in passing. At Trondhjem, moreover, on August 14, we had time, under Dr. Reusch's guidance, to visit the high strand-lines near the city and to examine the scientific and artistic collections in its museums, finishing the day with a pleasant reunion at one of the hotels. Here we left our ship, taking train on the morning of August 15 up the fine valley that leads across the Swedish frontier. We reached Åre in Jämtland in the afternoon, went eastward until evening across the ground we had seen from the summit of Areskutan, past the great Lake Storjon, and reached Stockholm, exactly on time, before breakfast on the morning of Wednesday, August 17. The initial reception of the members of the congress was held in Stockholm on the evening of that day.

To those who did not share in the pilgrimage this recital of our itinerary can at the best convey only a feeble idea of its advantages. Not the new country alone and the new experiences, but above all, the constant association and intercourse of men of different nationalities and outlooks, with interests in common which they were ever ready to discuss together—this it was that gave peculiar value to the journey, as to all journeys of the same type. Deeply indeed were we indebted to our leader, Prof. G. De Geer, and to the accomplished lady, his wife, for the whole-hearted enthusiasm which they threw into the difficult task of planning, guiding, and demonstrating in

Photo. by Oscar Halldin, Stockholm.] [*Reproduced by kind permission of Prof. G. de Geer.*

FIG. 3.—North end of Cora Island, Ekman Bay; showing the Sefström moraine of shelly clay, to the left of the inlet, and a portion of the original island to the right.

in time to make the ascent of Mt. Åreskutan (4620 feet) for the sake of the view from its summit over an immense range of lower lake-country to the eastward. The glacial phenomena of this region are like those of Torneträsk on a grander scale; the same evidence for a succession of glacier-dammed lakes, at first discharging westward over the watershed into Norway; the same shrinkage of the ice-sheet from the western mountain-rim to the lower eastern country; the same westward transport of the boulders. On the top of Åreskutan there are boulders which have come from places far away to the eastward at much lower altitudes.

In the evening Prof. C. Wiman joined us at Åre; and next morning, under his leadership, we visited sections near the Åre Lake, which show the fossiliferous Lower Palæozoic succession. We were able also to appreciate the evidence for a gigantic overthrust of the metamorphic rocks from the westward over the unaltered Palæozoics. Leaving Åre by train in the afternoon of August 16, we varied languages so that the time at our disposal should always be profitably spent; and even still more for the happy spirit of friendliness and geniality which they imparted to the whole expedition. Much also we owed to Mr. B. Högbom for his share in the direction of our party in Spitsbergen, and to Dr. Hj. Lundbohm, Prof. C. Wiman, and Dr. O. Sjögren for their aid in Sweden, while Mr. C. Carlzon and Mr. H. Ahlmann were our ever-obliging helpers and interpreters. In our admiration for the extraordinary skill with which every stage of the journey was arranged, we could not fail to recognise the thoughtful solicitude of our physician and treasurer, Dr. J. W. Nordenson, of whose high qualities as an organiser we had daily proof.

Brief must be our reference to the constitution of the party. The British geologists were lamentably few—G. A. J. Cole, A. P. Coleman, A. Strahan, and the writer—but, for the occasion, we will count with us also the U.S. Americans, R. S. Tarr, Miss F. Bascom, Miss Z. Baber, and Miss E. Rice. The German and Austrian

contingent was predominant, including (titles omitted) H. Credner, G. Gürich, K. Keilhack, A. Penck, A. Rothpletz, W. Salomon, K. Sapper, F. Wahnschaffe, and other well-known names. Among those from France were L. Carez, L. de Lamothe, E. de Margerie, and A. Offret; from Italy, S. Cerulli-Irelli and E. Mattirolo; from Portugal, J. Mendez-Guerreiro; from Switzerland, M. Allorge, J. Brunhes, and P. Mercanton. From Denmark, among others, came V. E. Hintze, V. Madsen, and J. P. J. Ravn; from Holland, J. I. J. M. Schmutzer and Mlle. A. Grutterink; from Norway, H. Reusch; from Hungary, E. de Cholnoky and E. de Maros; and Japan was represented by K. Inouye and H. Yabe. Broadcast now is the gathering that went with the good ship *Æolus* on this memorable voyage to Spitsbergen!

G. W. LAMPLUGH.

A FOURTH RECALESCENCE IN STEEL.

IN 1868 the late Dr. George Gore, F.R.S., discovered the recalescence points now known as Ar_3 and Ar_2, and in 1872 Prof. W. F. Barrett, F.R.S., discovered the point Ar_1, which is now known as the carbon change point. Prof. Barrett gave the phenomena the generic title of "recalescence," by which they have been known ever since.

Photo-micrograph of nearly Pure Iron containing 0·21 per cent. Carbon. Rapidly quenched between the two peaks of Ar_2. Magnified 450 diameters.

At the recent meeting of the British Association, Prof. J. O. Arnold described to the section of chemistry the result of accumulated thermal and micrographic observations upon this subject extending over twenty years. He first described the recalescence apparatus used at Sheffield University, in which the tape results can be plotted either as a time-temperature or as an inverse-rate curve. The latter is more delicate, its coordinates being units of temperature and time in seconds, for units rise or fall in temperature.

The Recalescence of Chemically Pure Iron.

From many observations it appears that before even a rough quantitative measurement of recalescence in steel can be made it is very desirable to obtain a standard cooling curve of iron absolutely free from carbon; this was made possible by a gift of chemically pure iron from Dr. Hicks and Prof. O'Shea, of Sheffield University. The recalescence data registered *in vacuo* on placing the thermocouple between two small plates of this iron show that the maximum of Ar_3 appears at 854° C., and the set-back between the two peaks of Ar_2 is registered at 750° C.

The Recalescence of Iron containing about 0·2 per cent. Carbon.

On cooling unsaturated steels containing about 0·2 per cent. carbon it was noticed that there was along the range of temperature between Ar_3 and Ar_1 some thermal evolution which prevented the curve crossing the radiation line after recalescence, and also kept it well to the right of that line. Careful investigation of this phenomena revealed the fact that whilst with iron containing 0·38 per cent. carbon this new and prolonged recalescence was very much augmented, as compared with a 0·2 per cent. carbon steel, that iron containing 0·63 per cent. carbon gives out during this fourth phase of recalescence much less heat than the 0·38 per cent. carbon steel. Therefore it would appear that the maximum of heat of the fourth phase of recalescence is evolved from a semi-saturated steel, namely, an iron containing 0·45 per cent. carbon, and having in the cold a micro-structure consisting of 50 per cent. ferrite and 50 per cent. pearlite. The recalescence data and curves of all these steels were shown on the screen and minutely described.

The Cause of the Fourth Phase of Recalescence.

By micro-thermal investigations Prof. Arnold has satisfied himself that the fourth phase of recalescence is due to constitutional segregation, namely, the falling out between Ar_3 and Ar_1 of the ferrite and hardenite from their state of mutual interpenetration or solid solution into microscopically invisible masses. A method was adopted for rapidly quenching from nitrogen in iced brine 0·2 per cent. carbon steel at various temperatures. The temperatures were:—(1) 995° C. (well above Ar_3); (2) just below Ar_3; (3) just after first peak of Ar_2; (4) just above Ar_1; (5) 15° (normalised or cooled in air).

The micrograph here reproduced is a section quenched between the two peaks of Ar_2. The segregation is obviously proceeding very quickly, and the ferrite is strongly electro-negative to the dark etching areas of hardenite still containing in solution large quantities of iron. The micrographs indicate that the critical range Ar_2 has no influence on the segregation of hardenite and ferrite. In Prof. Arnold's view these five photomicrographs, when correlated with the recalescence curves of the steel experimented upon, prove that the fourth phase of recalescence is due to the heat evolved during the segregation of the ultimate micrographic constituents of steel, which began at Ar_3 and incomplete at Ar_1, during the cooling of unsaturated steels at a moderate rate, say 0·5° per second.

REPORTS ON IMPERIAL FOODSTUFFS.

WE have received No. 63 ("Gums and Resins") and No. 71 ("Foodstuffs") of the "Colonial Reports: Miscellaneous," comprising selected reports from the Scientific and Technical Department of the Imperial Institute. They refer to products, from British possessions, examined at the institute with regard generally to the possibility of their profitable cultivation or preparation in the districts concerned. The first report is a useful little monograph on gums and resins from the commercial and analytical point of view, with particulars of the colonial specimens examined. The chief matter of scientific interest in the paper on foodstuffs, namely, a summary of the

facts relating to cyanogenesis in plants, has already been published elsewhere.

Among points of general interest we note that Yebb (or Yeheb) nuts from Somaliland, which grow in arid districts and have formed the principal food of many destitute refugees, were found to contain about 12 per cent. of albuminoids, 11 per cent. of oil, 24 per cent. of sugars, and 37 per cent. of other carbohydrates. They thus show high nutritive value as a foodstuff; and it is recommended that the cultivation of the plant (*Cordeauxia edulis*) producing the nuts should be tried in other countries, especially where a foodstuff is needed which can be grown in arid places. Tea from the Nyasaland Protectorate was found to be analytically of good quality, though on account of its having been packed with tobacco no opinion could be given on its flavour. Nevertheless, it is considered that the cultivation of tea in the Protectorate might well be extended. Some Natal tea, too, appears to be very satisfactory. Its proportion of caffeine is only slightly less than that of Indian tea examined, and as regards tannin it is intermediate between Indian and China teas. In the opinion of the department the cultivation and preparation of tea in Natal deserves very full study, with a view to the production of tea of characteristic quality.

Cocoa grown experimentally in Uganda gave very promising results. So also did some specimens cultivated by the Botanical Department of the Gold Coast Colony, though it was pointed out that more attention was required in the fermentation of the beans, since it is on this that the aroma and colour largely depend. Small consignments subsequently sent for actual sale realised fair prices, and from the knowledge gained it was possible to indicate the directions in which further improvement of the cocoa could be effected. Some useful memoranda on miscellaneous matters, such as the constituents of food and their functions, and the harvesting and shipment of maize, are also included in this report on foodstuffs.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The special board for medicine has elected Prof. Marsh, Master of Downing College, as its representative on the general board of studies for four years, and the special board for economics and politics has elected Mr. G. L. Dickinson as its representative on the same board for the same period.

Prof. Hughes states that he has received a very valuable gift of fossils, &c., from the widow of the Rev. G. F. Whidborne, who had previously presented to the Sedgwick Memorial Museum the collection of Devonian fossils which he had described in the Transactions of the Palæontographical Society. Mrs. Whidborne has now given to the museum the remainder of his collection, with all his scientific books and manuscripts, together with a valuable series of photographs and other illustrations, and has included in her gift the cabinets in which some of the specimens were kept and were being arranged.

The Vice-Chancellor publishes the following extract from the will of the late John Willis Clark, formerly Registrary of the University:—"I bequeath also to the Chancellor, Masters, and Scholars of the University of Cambridge my Collection of Voyages and Travels as recorded in a special catalogue, forming part of the collection, to be placed under the charge of the Museums and Lecture Rooms Syndicate. And I request the said Syndicate to deposit the same wherever in their judgment it is likely to be most useful."

The board of anthropological studies desires the establishment of a special examination in anthropology for the ordinary B.A. degree. The board reports as follows:—"As anthropology is a subject that is rapidly growing in importance, the board is of opinion that the time has arrived when it is desirable that a special examination in anthropology should be held. Anthropology is a science that demands extensive and precise study, and at the same time bears upon other branches of learning, for example, history, economics, psychology, biology, and geography. It may now be considered as a mental discipline not inferior to other subjects comprised in the various special examinations."

OXFORD.—On November 29 Congregation took into consideration some of the amendments that had been proposed to the statute concerning the faculties and boards of faculties, of which the preamble was approved on November 8. Exception had been taken in some quarters to certain provisions of the statute which appeared to disqualify the college tutors as such for membership of the faculties. An amendment proposed by the Master of Balliol providing that the head of any college or similar society within the University might certify any member of Convocation authorised by his society as a member of the faculty in which his teaching is given was carried without a division. Another amendment, proposed by the Master of University College, to the effect that a number of the members of the general board of the faculties should be elected from and by the whole body of members instead of from and by each faculty acting separately, was opposed by the President of Magdalen, Prof. Gotch, F.R.S., and Prof. Oman, and rejected on a division.

As was generally anticipated, the question of compulsory Greek is not to be allowed to rest in the position to which it was relegated by the division on November 22. A petition to council is being prepared, asking that a short statute may be framed relieving honour students in the schools of natural science and mathematics "from the necessity of taking two ancient languages in Responsions." This movement has the support, amongst others, of Sir W. Anson, Profs. Gilbert Murray, Myres, Poulton, F.R.S., H. H. Turner, F.R.S., and Osler, F.R.S., the latter of whom, however, has stated "that he is strongly in favour of retaining Greek in the case of candidates for the degrees in medicine."

MR. JAMES A. PATTEN, of Chicago, says *Science*, has given 40,000*l*. to endow a chair of experimental pathology in the medical school of Northwestern University. Special attention is to be directed to the study of tuberculosis and pneumonia. By the will of the late Mr. S. W. Bowne, bequests in stocks and bonds of considerable value are made to Wesleyan University and Dickinson College. Radcliffe College, we learn from the same source, has received from Mrs. Martha T. Fiske Collard a bequest amounting to about 20,000*l*.

M. MAURICE LERICHE has been appointed professor of geology at the University of Brussels. M. Leriche has been until recently "Maître de Conférences" at Lille University. He has recently issued an important monograph on the Oligocene fish of Belgium, published in the *Mémoires du Musée Royal d'Historie Naturelle de Belgique*, v. Prof. Dollo retains the chair of palæontology at Brussels University and conservator of the department of vertebrate remains of the Brussels Museum, and thus will continue in charge of the important collections which his work has rendered famous.

PRINCE ARTHUR OF CONNAUGHT has accepted the position of president of the appeal committee appointed to secure the sum of 70,000*l*. for the purchase of the site in Gower Place and for the erection thereon of new chemical laboratories for University College, London. We are glad to notice that the new president in a further appeal through the Press emphasises the national aspect of the appeal committee's object, and asks for a national response. As we have pointed out already, 25,000*l*. must be raised before December 25 next if the new site is to be secured, and towards this amount upwards of 10,000*l*. has been raised. It should not be difficult to secure the remaining 15,000*l*. during the next few weeks.

THE German Emperor opened a new technical university at Breslau on Tuesday, November 29, and delivered an address, in which he referred to the great importance of such institutions for the industrial progress of the Empire. There are now eleven technical universities in Germany, five of which are in Prussia, namely, at Charlottenburg, Aachen, Hanover, Danzig, and Breslau. The Berlin correspondent of the *Morning Post* reports that in the course of his remarks at the dedication of this—the second technical university founded in his reign—the German Emperor said:—"The close connection between

technical science and industry becomes year by year more manifest, and it is not by chance that the immense advance made by our industrial life is contemporaneous with the progressive development of the technical university system in Germany. The times are past in which a school of practice sufficed for the engineer. Whoever wishes to be equal to the demands made by technics in our time must go into the battle of life equipped with a solid scientific and technical education." His Majesty also remarked that Silesia had gained for itself an eminent position through the assiduity and spirit of enterprise which had enabled it to develop its coal and iron and its spinning and weaving industries, and he expressed the opinion that the inhabitants were perfectly justified in desiring to have a technical university in their capital. Dr. von Trott zu Solz, Prussian Minister of Ecclesiastical Affairs, addressing the Emperor, recalled the fact that it was King Frederick the Great who laid the foundation of the greatness of the Silesian industries, in that he encouraged the employment of Silesian coal in other industrial districts and overcame the prejudice against Silesian iron.

A CONFERENCE organised by the Joint Committee for the Abolition of Half-time Labour was held on November 23 at the Church House, Westminster, with the Bishop of Birmingham in the chair. The meeting was called to consider the question of the employment of children in mills and factories, and of securing the passage of a Bill through Parliament raising the age of "half-timers" to thirteen. Prof. Sadler, in a letter expressing inability to attend, said it is a drag upon the economic welfare of the country that more than 200,000 children between twelve and fourteen years of age have left the day school for good, and that more than 40,000 more only attend school half time. There is no reason in the nature of things why the number of boys and girls under fourteen who are wholly or partially exempt from day-school attendance should be proportionately six times as numerous in England and Wales as in Scotland. The chairman insisted that it is a ludicrous waste of energy and money to let education stop at the age of fourteen, thirteen, or twelve. The evil is increased by the system of half-time attendance. Two things, he said, are necessary to stop this wastage of education—to abolish the half-time system, except possibly in some very extreme and exceptional circumstances, and to press forward in the matter of continuation schools. If continuation schools are to be made a real force, the hours of work in shops must be restricted. It is physiologically certain that it is impossible to get real good out of education so long as the bodies and minds of children are in the main occupied in getting a living. Eventually the following resolution, which was proposed by Lord Sheffield, was carried:—"That this meeting approves of the recommendations of the Departmental Committee on partial exemption, and trusts that legislation, as promised by the Board of Education and unanimously approved by resolution by the House of Lords, may be carried into effect in the first session of the coming Parliament."

IN consequence of a suggestion of the Chancellor of the Exchequer made last March to a large deputation from English universities and colleges, a committee of representatives from these educational institutions was appointed to place before the Chancellor suggestions as to the principles of distribution on which, in its opinion, an additional grant to university Colleges might be utilised most effectively. The committee consisted of Mr. A. H. D. Acland, Sir Alfred Hopkinson, F.R.S., Sir Oliver Lodge, F.R.S., Sir Isambard Owen, and the Rev. Dr. A. C. Headlam. Conferences between the Chancellor of the Exchequer and the President of the Board of Education with the committee were held on November 16 and 17. The committee expressed the view that the Treasury Committee, on the advice of which grants are distributed, should take into consideration:—(1) Output.—That is, the extent and character of the work being done, including the number of students, the nature of the instruction given, and research and other work undertaken. (2) Needs in order to carry on the work efficiently: (*a*) staff, and the remuneration of its members: (*b*) accommodation and equipment. (3) Development.—The development of work which the several universities and colleges desire, and would be in a position to undertake effectively with further financial assistance, and having regard to provision already made from private benefactions, or other local support, or which may be obtained for such objects. The committee also pointed out it is essential for the universities and colleges to have freedom as to the mode of expenditure of grants to secure the greatest return from them and to meet constantly varying conditions. Great importance was attached to the grants being certain, and not liable to diminution, so long as the extent and character of the work are maintained. The Chancellor of the Exchequer expressed himself willing to grant an additional sum to the colleges to be allocated on the lines laid down by the committee, but subject to the condition that sufficient additional local support is forthcoming in each case, not only to maintain the existing activities of the college in conjunction with its existing Treasury grant and to place it on a secure footing in regard to its capital liabilities and requirements, but to meet a suitable proportion of the cost of maintenance of the new developments adopted. He was prepared to increase the total grant by 50,000*l.*, and promised (subject, of course, to compliance with the minimum conditions as to character, efficiency, &c., which any college is already required to fulfil in order to participate in the grant at all) not to reduce the existing grants to the several colleges.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, November 9.—Prof. W. W. Watts, F.R.S., president, in the chair.—L. **Richardson**: The Rhætic and contiguous deposits of west, mid, and part of east Somerset. This paper contains an account of the Rhætic strata of Somerset. The sections at Blue Anchor and Lilstock are described and correlated with those on the Glamorgan coast. The record by Prof. Boyd Dawkins of Rhætic mollusca in the top portion of the Grey Marls is confirmed, and their recognition as Rhætic is substantiated. The deposit between the top of the fossiliferous Grey Marls or "Sully beds" and the main bone-bed at Blue Anchor measures 22 feet, and teems with Rhætic fossils. The beds above the bone-bed agree well with those occupying the same stratigraphical position in Glamorgan. The now obscured sections, that were to be seen in the railway-cuttings at Langport and Charlton Mackrell, noticed by Mr. H. B. Woodward, are described. Huge boulder-like masses of rock were noted at the top of the Black Shales, and the White Lias proper, with a well-marked coral-bed, totalled 25 feet in thickness. The classic sections of Snake Lane, Dunball (Puriton), Sparkford Hill (Queen Camel), Shepton Mallet, and Milton (Wells), have been reinvestigated, and the thin Rhætic deposits in Vallis Vale, at Upper Vobster, and sections in the Radstock district, and on the Nempnett and neighbouring outliers, are described. This investigation has shown that the Microlestes Marls are equivalent to the Sully beds; that the Wedmore Stone occurs well below the bone-bed; that Moore's "flinty bed" at Beer Crowcombe is probably on the horizon of the Pleurophorus bed (No. 13); that the Upper Rhætic is as persistent as usual; that the White Lias proper is of restricted geographical extent: and that on the Bristol Channel littoral are marls, "Watchet beds," above the White Lias. Around Queen Camel, Moore's "insect and crustacean beds" appear to come in at a horizon which lies between the Watchet beds and the Ostrea Limestone. A classification of the Rhætic series is suggested. The fauna of the Rhætian is Swabian in facies, and the conclusion to be derived from the study of the beds is in agreement with Suess's view, that while the dominant movement was one of subsidence and not local but extended, it was, nevertheless, "oscillatory and slow."—Rev. G. J. **Lane**: Jurassic plants from the Marske quarry. The Marske quarry is situated on the northern side of the Upleatham outlier in the Cleveland district of Yorkshire. In the quarry several varieties of rock are

exposed, namely, shales, small coal-seams, sandstones, and a ferruginous bed. The beds are of Lower Oolite age, and belong to the Lower Estuarine series. From this quarry Dictyozamites was recorded for the first time in England. The writer has obtained nearly forty species from the quarry, among which are many characteristic Wealden plants.

Physical Society, November 11.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Dr. C. **Chree**: The supposed propagation of equatorial magnetic disturbances with velocities of the order of 100 miles per second. The question of the simultaneity of magnetic disturbances recorded at different stations has recently been discussed by Dr. Bauer and Mr. Faris. A good many magnetic storms have so-called "sudden commencements." As regards these "sudden" changes, three things are conceivable: they may be absolutely simultaneous at different stations; there may be a very small difference of time corresponding to the rate of propagation of electromagnetic waves; or, finally, there may be, as Dr. Bauer concludes, longer intervals, amounting to several minutes, for stations remote from one another. Dr. Bauer concludes that Mr. Faris's figures demonstrate the truth of his theory that disturbances normally are propagated round the earth, sometimes eastwards, sometimes westward, the time of a complete revolution averaging about 3¾ minutes. The author of the present paper discusses the weaknesses of Dr. Bauer's theory. He points out that the theory could be adequately tested by a careful comparison of curves from selected stations fairly encircling the globe, choosing, if possible, stations the time-measurements of which are specially trustworthy.—Prof. W. B. **Morton**: Cusped waves of light and the theory of the rainbow. Diagrams were shown of the forms assumed by a plane wave of light falling on a spherical raindrop and twice reflected from the interior of the drop, as well as the waves emerging from the drop. The waves in general have cuspidal edges, which run along the caustic surfaces. This relation between the caustic and the cusps on the waves was pointed out by Wood in connection with the similar waves produced by reflection at a spherical surface. It had been noticed earlier by Potter, Jamin, and Macé de Lepinay. The phase over a wave of this type is not constant, the two portions on opposite sides of a cusp differing in general by a quarter period. Attention was directed to the advantage of regarding the distribution of light in the rainbow as the consequence of the interference of the cusped waves which run down to the observer's eye along the direction of minimum deviation. This way of looking at the matter is shown to be equivalent to Mascart's approximate method of explanation of the formation of the supernumerary bows by interference of disturbances coming from the two poles on the special wave-form used by Airy.

Zoological Society, November 15.—Dr. S. F. Harmer, F.R.S., vice-president, in the chair.—J. Lewis **Bonhote**: Experiments on the occurrence of the web-foot character in pigeons. After referring to Mr. R. Staples Browne's paper on the subject in the Proc. Zool. Soc. for 1905, in which the web-foot was shown to be a simple Mendelian recessive, Mr. Bonhote instanced further cases from the lofts of Mr. F. W. Smalley that bore out Mr. Staples Browne's conclusions. Both these gentlemen, however, gave the author birds from their strains, and in the first instance when webbed birds from the different strains were crossed an irregular result—namely, four normal and one webbed—was obtained. Matings from these birds were continued, and the results were, in almost every case, contrary to Mendelian expectations, normals throwing webs and webs throwing normals. After discussing various suggestions, Mr. Bonhote came to the conclusion that no really satisfactory explanation was forthcoming. The Mendelian inheritance was apparently there, but dominated and modified by some other agency.—E. **Degen**: Notes on the little known lizard *Lacerta jacksoni*, Blgr., with special reference to its cranial characters.—G. A. **Boulenger**: *Lacerta peloponnesiaca*, Bibr. A new description of this little known lizard, made from living specimens in the society's gardens, with the view of fixing its correct position in the genus Lacerta.—E. G. **Boulenger**: Remarks on two species of fishes of the genus Gobius, from observations made at Roscoff. The paper dealt with the specific distinction of *Gobius minutus* and *G. microps*.

Linnean Society, November 17.—Dr. D. H. Scott, F.R.S., president, in the chair.—Prof. G. **Henslow**: A theoretical origin of *Plantago maritima*, L., and *P. alpina*, L., from *P. Coronopus*, L. Vars. This suggestion arose from the presence of *P. maritima* around the erection of faggots for condensing the brine of the salt-spring of Bad Nauheim, which is some 240 miles from the nearest coast, for M. Lesage proved that fleshiness of maritime plants was the direct result of the presence of salt. *P. Coronopus* has many varieties, and all the characters upon which they are based are very variable; forms approximating the above species are already named.—Prof. G. **Henslow**: A theoretical origin of Monocotyledons from aquatic Dicotyledons through self-adaptation to an aquatic habit, being supplementary observations to a previous paper (Journ. Linn. Soc., Bot. xxix. [1892], p. 485). The conclusions arrived at are:—(1) Coincidences are innumerable in all parts of monocotyledonous plants with aquatic Dicotyledons. (2) Experimental verification now covers and explains a large proportion of these coincidences. (3) Terrestrial Monocotyledons retain by heredity many of the aquatic characters acquired by their ancestors when living a hydrophytic life, but they are now readapted to a life in air.

MELBOURNE.

Royal Society of Victoria, October.—Prof. E. W. Skeats in the chair.—T. S. **Hall**: The systematic position of the species of Squalodon and Zeuglodon described from Australia and New Zealand. *Squalodon wilkinsoni*, McCoy, *Zeuglodon harwoodi*, Sanger, *Kekenodon onamata*, Hector; and *Prosqualodon australis*, Lydekker, agree in having the molar roots fused, as distinct from the northern hemisphere forms. New genera based on the proportion of crown to fang are proposed, namely, *Parasqualodon* (*wilkinsoni*) and *Metasqualodon* (*harwoodi*).—C. M. **Maplestone**: Further descriptions of the Tertiary polyzoa of Victoria, part xi. A new family, Synapticellidæ, with n.g. Synapticella (6 spp.), is founded. The family is allied to Catenicellidæ and Eucratidæ, but the zoaria are free and rigid, and the zoœcia in single series. In all, 38 new species are described.—F. **Chapman**: A trilobite fauna of Upper Cambrian age (Olenus series) in N.E. Gippsland, Victoria. E. O. Thiele found a limestone near Mt. Wellington which he, Skeats, and Dunn hold to be interbedded in slates which on graptolite evidence are Upper Ordovician. The author records Agnostus, Crepicephalus, and Ptychoparia, besides brachiopods and a few other forms, all of which are held to show Cambrian affinities.—A. J. **Ewart**, Jean **White**, and Bertha **Wood**: Contributions to the flora of Australia, No. 16. The authors described a new grass, Sarga, n.g., from N.W. Australia, a new Linum from Tasmania, and others.

CAMBRIDGE.

Philosophical Society, November 14.—Prof. Wood in the chair.—Prof. **Biffen**: Some crosses with Rivet wheat. Cases of coupling of roughness of the chaff with grey colour were described from several crosses between subspecies of *Triticum sativum*, and also a case where two varieties normally immune to the attacks of *Claviceps purpurea* gave rise to an F_2 generation containing susceptible individuals.—Mrs. D. **Thoday** and D. **Thoday**: The inheritance of the yellow tinge in sweet-pea colouring. The yellow tinge in scarlet, salmon, and deep cream sweet peas is found to be very complex in character. In the deepest tinged flowers examined, Queen Alexandra and St. George, the yellow colouring is produced by at least three coincident recessive factors. The three are all independent of one another; two tinge the sap and affect the whole flower, while the third is a plastid character, especially affecting the standard and pro-

ducing marked bicoloured forms. In the absence of yellow plastids the flowers do not "burn," unlike most known salmon or scarlet varieties.—Dr. R. N. **Salaman**: Demonstration of Mendelian laws of heredity in the potato.—Prof. **Wood**: The feeding value of mangels. Reference was made to a former communication on the composition of the five types of mangels. The present paper describes a series of feeding trials designed to ascertain if the percentage of dry matter is a fair index of feeding value. Nine experiments are discussed, and the result arrived at is that the percentage of dry matter does indicate the feeding value.—F. H. A. **Marshall**: Some causes of sterility in cattle. Sterility in some cases was shown to be probably due to a deposition of lipochrome in the ovarian interstitial tissue, associated with follicular degeneration.—F. H. A. **Marshall** and K. J. J. **Mackenzie**: Caponising. It was shown that in a case of incomplete caponisation, where pieces of testis of varying sizes had become transplanted on to the intestine and in other abnormal positions, spermatozoa were formed in the testicular grafts in spite of the fact that they were virtually ductless glands; also that the development of the secondary male characters and sexual desire were almost normal, as in the cases described by Foges and Shattock and Seligmann.—F. W. **Foreman**: Notes on protein hydrolysis. During the hydrolysis of the protein of Linseed the following points worthy of special mention were noted:—(1) By a modification of the ordinary method it was found possible to separate practically the whole of the glutaminic acid as the hydrochloride in the early stages of the hydrolysis. (2) The very high content of valin compared with leucin. (3) The low percentage of tyrosin. (4) The discovery of a basic lead salt of tyrosin, and the possibility of introducing a trustworthy method for the estimation of tyrosin in a mixture of amino-acids obtained from a protein by hydrolysis by precipitating it as this basic lead salt.—K. R. **Lewin**: Nuclear relations of *Paramecium caudatum* during the asexual period. The micronucleus of *Paramecium caudatum* is not necessary to continued multiplication by fission. By merotomy an amicronucleate race was obtained which maintained itself for seven weeks. This result was not due to fusion of mega- and micronuclei under the stimulus of operation.

DUBLIN.

Royal Dublin Society, November 22.—Prof. T. Johnson in the chair.—Prof. W. **Brown**: Mechanical stress and magnetisation of nickel. The author gave the results of experiments on magnetism and torsion of nickel wires when the wires were of different degrees of magnetic softness and of different lengths and diameters, which show several peculiarities in the behaviour of nickel as compared with iron when tested under the same conditions.—Prof. T. **Johnson**: A seed-bearing Irish pteridosperm—*Lyginodendron Oldhamium*, Willm. The author records the presence in Ireland of the Pteridospermeæ, and gives an account of specimens of *Sphenopteris Hoeninghausi*, Brgt., in the botanical division of the National Museum, Dublin, and especially of one specimen of this in the Geological Survey collection. This specimen shows not not only the connection of *S. Hoeninghausi* with the stem of Lyginodendron, but also the direct continuity of the fossil known as *Calymmatotheca Stangeri* with *Lyginodendron rachis*. In addition the author describes the presence of a Lagenostoma seed in one of the cupular rosettes of Calymmatotheca. The specimen furnishes the evidence of direct continuity in support of the views of Oliver and Scott on the synthetic reconstruction of the Palæozoic pteridosperm *Lyginodendron Oldhamium*.

PARIS.

Academy of Sciences, November 21.—M. Émile Picard in the chair.—M. Francotte was elected a correspondant in the section of anatomy and zoology in the place of the late M. Van Beneden.—J. **Guillaume**: Observations of Cerulli's comet made at the Observatory of Lyons. Data are given for November 12 and 16. The comet is of about the tenth magnitude; a small tail was visible on November 16th.—M. **Luizet**, J. **Guillaume**, and J. **Merlin**: Occultations observed during the total eclipse of the moon of November 16, 1910, at the Observatory of Lyons.—L. **Montangerand**: Observation of the total eclipse of the moon of November 16, 1910, made at the Observatory of Toulouse.—M. **Lebeuf**: The total eclipse of the moon of November 16, 1910, observed at the Observatory of Besançon by MM. Chofardet and Goudey.—M. **Bourget**: Observations of the total eclipse of the moon of November 16, 1910, made at the Observatory of Marseilles.—Robert **Jonckheere**: The total eclipse of the moon of November 16–17, 1910, at the Obervatory of Hem.—E. **Cartan**: Isotropes capable of development and the method of the mobile trihedron. Eugène **Fabry**: Order of the singular points of a Taylor's series.—A. **Chatelet**: The theory of numbers.—T. **Lalesco**: Resolving nuclei.—Marcel **Brillouin**: The discontinuous movement of Helmholtz. Curved obstacles.—M. **Villat**: The resistance of fluids limited by a fixed indefinite wall.—MM. **Claude**, **Ferrié**, and **Driencourt**: Telephonic and radio-telegraphic comparisons of chronometers by the method of coincidences between Paris and Brest. The difference between the two sets of comparisons by telephone and by wireless telegraphy is less than 0·01 sec.; if necessary, the accuracy could be increased.—G. A. **Hemsalech**: The modifications undergone by the lines of the spark spectrum in a magnetic field. A development of work described in a previous paper. Three classes of phenomena are shown to exist: a general effect independent of the direction of the lines of force of the magnetic field; a longitudinal effect, produced when a spark is parallel to the lines of force; and a transversal effect, produced only with very slow discharges, when the spark is perpendicular to the lines of force. In the present paper observations on the first two of these effects are described and discussed.—G. A. **Andrault**: A rapid graphical method for measuring the slipping of induction motors.—Francisque **Grenet**: Study of the porosity of Chamberland filters. The dry filter, placed vertically, is completely filled with mercury, and a fine steel tube passed through a close-fitting stopper is connected with a calibrated glass capillary tube. On plunging the filter into distilled water, the air in the capillaries of the porous pot is driven inwards, causing a rise of the mercury in the glass capillary. Filter tubes of different makes showed large differences in the pressures thus measured, varying from 18 cm. to 2 metres of mercury. These pressures measure the diameters of the pores of the filter.—J. **de Kowalski** and J. **de Dzierzbicki**: The progressive phosphorescent spectrum of organic compounds at low temperatures. Figures are given for the bands of benzene and nine of its homologues, for phenol, cresols, and xylenols and benzyl alcohol. The results show that progressive phosphorescence is a property which depends essentially on the constitution.—Charles **Moureu** and J. Ch. **Bongrand**: Propiolic compounds. Cyanacetylene. Methyl propiolate, $CH{:}C.CO_2CH_3$, was converted into propiolamide, $CH{:}C.CO.(NH_2)$. By the action of phosphorus pentoxide upon this amide, cyanacetylene, $HC{:}C—CN$, is obtained. This forms a mobile liquid boiling at 42·5° C., solidifying in ice to a mass of crystals melting at 5° C. The physical and chemical properties of this compound are given in detail.—Casimir **Cépède**: An improvement of the binocular microscope, increasing the illumination of the objects under observation.—Marcel **Mirande**: The effects of tarred roads on vegetation. It has been found experimentally that the vapours given off by tar such as is used for treating roads act injuriously on green plants. In the open country the vapours given off by a tarred road would be insufficient to damage vegetation, but in shut-in streets damage to trees planted on the edge of the pavement may be expected.—Jules **Amar**: Respiratory exchanges after work has been done. The amount of oxygen used by a human subject was measured, first, when at rest, then during work, and finally at regular intervals after cessation of the work. The original consumption of oxygen was reached in from six to eight minutes after the work was stopped. The rate of decrease of oxygen absorption varied with each subject.—Ch. **Gravier**: The battle for existence in the

madrepores of coral reefs. The forms which succumb in the struggle are those which are large and globular; the arborescent forms have more resisting power.—E. **Roubaud**: The evolution and history of *Roubandia rufescens*, a parasite of the social African wasps, genera Icaria and Belonogaster.—P. **Fabre-Domergue** and R. **Legendre**: The search for *Bacterium coli* in sea water by the methods employed for fresh water. All the usual tests for coli in fresh water are retarded in their action by the presence of common salt. Certain modifications of technique necessitated by this fact are suggested. The question has arisen in connection with the control of oyster beds.—J. **Couyat** and P. H. **Fritel**: The presence of plant impressions in the Nubian grit in the neighbourhood of Assouan.

CAPE TOWN.

Royal Society of South Africa, October 19.—Mr. S. S. Hough, F.R.S., president, in the chair.—A. G. **Howard**: An investigation into the land and sea breezes conditions at Port Elizabeth. A second contribution to the meteorology of South Africa.—E. T. **Littlewood**: Graphical representation of some of the simpler analytic functions of a complex variable. The modulus of the function corresponding to each point of the (horizontal) xy plane was represented by the length of a vertical line erected at that point, the upper extremities of these lines forming a ("modular") surface, while the argument was represented by a family of curves ("stream lines") drawn in the xy plane. Certain general results were established and methods given. In the models, the surface was suggested by a wire framework, which usually illustrated contour lines and vertical sections, while the stream lines, drawn on the horizontal base of the model, were visible through the framework. The simpler algebraic, circular, exponential, and logarithmic functions were thus treated.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 1.

LINNEAN SOCIETY, at 8.—Spermatogonesis in Stenobothrus: Capt. C. F. U. Meek.—Reports on the International Botanical Congress at Brussels, 1910: Dr. Otto Stapf and others.

RÖNTGEN SOCIETY, at 8.15.—Osmotic Growths: Dr. Deane Butcher.

FRIDAY, DECEMBER 2.

GEOLOGISTS' ASSOCIATION, at 8.—The Geology of Natal: Dr. F. H. Hatch.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Scherzer Rolling-lift Bridge over the River Tawe, at Swansea: J. H. Morris.

MONDAY, DECEMBER 5.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Geographical Aspects of the Problem of Empire Cotton Growing: J. Howard Reed.

ROYAL SOCIETY OF ARTS, at 8.—Industrial Pyrometry: C. R. Darling.

ARISTOTELIAN SOCIETY, at 8.—A Defect in the Current Logical Formulation of the Basis of Induction: Bernard Bosanquet.

VICTORIA INSTITUTE, at 4.30.—The Theory of Jurisprudence: Judge G. H. Smith.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The Analytical Constants of Shellac, Lac-resin and Lac-wax: Puran Singh.—Theory of Dyeing: Resolution after Treatment with Acids, &c.: W. P. Dreaper and A. Wilson.—Some Indian Oils and Fats: A. Kesava Menon.

TUESDAY, DECEMBER 6.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Further discussion*: Portland Cement, and the Question of its Aeration: H. K. G. Bamber.

WEDNESDAY, DECEMBER 7.

ROYAL SOCIETY OF ARTS, at 8.—The Panama Canal in 1910: Dr. Vaughan Cornish.

SOCIETY OF PUBLIC ANALYSTS, at 8.—On Fischer's Modification of Volhard's Method for the Estimation of Manganese, and its Comparison with other well known Methods: E. Cahen and H. F. V. Little.—Note on the Composition of British Wines: E. Russell and T. R. Hodgson.—A New Volumetric Process for the Estimation of Tungsten: Dr. E. Knecht and E. Hibbert.—A New Volumetric Process for the Estimation of Molybdenum: Dr. E. Knecht and F. W. Atack.—The Degree of Accuracy with which the Proteins of Milk can be Estimated by the Aldehyde Method: H. D. Richmond.—Note on Gorgonzola Cheese: E. Hinks.—Tests for Cocaine and certain Cocaine Substitutes: Dr. E. H. Hankin.

CONTENTS. PAGE

THURSDAY, DECEMBER 8, 1910.

FRESH-WATER FISH-CULTURE IN FRANCE.

Encyclopédie agricole. Pisciculture. By Georges Guénaux. Introduction by Dr. P. Regnard. Preface by M. Charles Deloncle. Pp. xii+489. (Paris: Baillière et Fils.) Price 5 francs.

THIS is a comprehensive, compact, and eminently practical handbook on all matters relating to fresh-water pisciculture. Much of the information and criticism which it contains applies almost equally to England as to France, since most of the fishes dealt with are found in our islands, and the almost complete neglect of fresh-water pisciculture—except in the case of the Salmonidæ—is as characteristic of this country as of that. What is true of the depopulation of the French watercourses is partly true of our own. In France the depopulation and its neglect were due partly to obvious causes inseparable from industrial progress, such as the opening of canals, the development of navigation, and the establishment of manufacturing works and chemical factories on the river banks, and partly to lack of enthusiasm following on historical events. The means adopted to arrest the depopulation, much less to restock the waters, have been, and continue to be, utterly disproportionate to the extent of the waters and to the magnitude of the task.

The results of this neglect are:—(1) That France consumes extremely little fresh-water fish, either absolutely, or relatively to the consumption of marine species; and (2) that the great bulk of what little she does consume is derived from adjacent countries, principally Germany, where the rearing of carp especially has been developed into a paying industry by long years of experience and the application of scientific methods. While it is possible, as hinted by the author, that a protective tariff might do a little to obviate this unsatisfactory state of affairs, the only complete solution of the problem is for France to grow her own fish. These French watercourses (our own rivers and broads also to some extent) are capable of producing an abundance of highly nutritious food. In both countries there are numerous fresh-water species the *chaire* of which, M. Guénaux assures us, is *excellente,* and would form a pleasing variant to the marine species which at present more or less flood the fish markets and almost exclusively appear on our tables. Clearly something should be done to develop this branch of food production, and to some extent M. Guénaux's practical text-book points the way.

But although fresh-water fish-culture is in the main neglected in France, there are a few salmon- and trout-hatching establishments, which seem to cost very little and pay remarkably well; also several laboratories connected with schools of agriculture, which contribute to the repopulation of the waters. Finally, attached to the Universities of Grenoble, Clermont-Ferrand, Toulouse, and Dijon are scientific laboratories for the study of fresh-water biology which pursue a double aim, scientific and practical. The University of Toulouse in particular has a large institution, started in 1903, devoted entirely to fresh-water pisciculture and hydrobiology, with museums, aquarium, and laboratories. In this matter England has something to learn from France, since, to the best of the reviewer's knowledge, the only station devoted to fresh-water hydrobiology in this country is a small private one on a Norfolk broad.

In writing a book on the whole subject it has been necessary for its author to combine the knowledge and qualities of a naturalist with those of an engineer and "practical man." This unusual demand on one's capacity and versatility has been met by M. Guénaux with conspicuous success. A critical inspection of the text of this book shows that its author is almost equally familiar with the morphological characteristics, taxonomic relations, and bionomical reactions (including feeding and spawning habits and requirements) of each species of fresh-water fish as he is with the merits and demerits of different kinds of salmon ladders, or the latest devices connected with egg-hatching apparatus, while he is evidently thoroughly *au fait* with the French laws relating to fresh-water fisheries, the weaknesses of which legislation he criticises in a characteristically practical manner.

The book opens with a brief account of the general anatomy of fishes, proceeding to take up each group in its natural order, explaining their taxonomic relations, and then giving a concise description (with good figures) of the distinguishing features and natural history of all the principal species, the most important features, namely, the feeding and spawning peculiarities of each, receiving particular attention. Then follows the subject of pisciculture proper, which forms the bulk of the volume. There are two kinds of pisciculture—natural and artificial. The object of natural pisciculture is to multiply the more valuable species by favouring their conditions of existence. Under this heading come such matters as the effects of navigation, canal-making, and industrial works, and the methods of combating these effects, and of restoring natural conditions, the planting of canals and dykes with plants on which the useful species may deposit their eggs, or seek shelter, the erection of ladders, and the construction of ponds, &c. By "artificial pisciculture," on the other hand, is meant the artificial fertilisation and hatching of the ova and the subsequent rearing of the fry. With the principal technical details of both kinds of pisciculture M. Guénaux deals exhaustively in a methodical and discriminating manner. As has been said, this is a thoroughly practical handbook, abounding in figures from statistics, measurements, and the critical comments of one who has had much first-hand experience of every branch of the business. There are plenty of good wood-cuts to illustrate construction of apparatus, &c. A succinct but fairly comprehensive account of aquatic invertebrate fauna and the flora next follows, and there is, finally, an excellent section on the parasitic diseases of fresh-water fishes and of injurious insects, reptiles, birds, and mammals. These chapters are also amply illustrated.

But even M. Guénaux's knowledge and versatility

have their limitations, and when he passes from fresh to salt water (metaphorically speaking) he appears somewhat "out of his element." Otherwise he would not have quoted antiquated and rejected notions regarding the growth of salmon after its migration to the sea in the face of the well-ascertained results of a vast amount of more recent research. Again, the author's account of the life-history of the eel is not abreast of current knowledge, since he makes no mention of the most important and not so very recent discovery of the breeding-grounds of this species all along the eastern shelf of the Atlantic basin. Reading M. Guénaux's account, one would suppose that the latest word on the subject of the eel had been said by Signors Grassi and Calandruccio, which is not so.

Then, again, the fear (casually expressed, it is true) lest certain species of pelagic sea fishes, such as the pilchards (sardines) off the west coast of France, be in danger of extermination through over-fishing is probably unwarranted, and argues a lack of knowledge of the conditions of life in the sea. Finally, returning to the salmon, it will surely surprise anyone who has some knowledge of the Highlands of Scotland and of the rigorous restrictions to which salmon-fishing is subjected in this region at the present day, to be told that:—

"*Aujourd'hui,* c'est dans ce pays [viz., Scotland] que les domestiques sont obligés de stipules à l'avance que le saumon no paraîtra trop fréquemment dans leur ordinaire!"

These happy days are almost ancient history. But such matters are, after all, quite on the fringe of M. Guénaux's subject. Enough has been said to indicate that the book is a small mine of information, and should be consulted by all whose business or pleasure brings them face to face with any of the difficult problems connected with fresh-water pisciculture.

WILLIAM WALLACE.

A CYCLOPÆDIA OF AGRICULTURAL CHEMISTRY.

Kleines Handwörterbuch der Agrikulturchemie. By Dr. Max Passon. Two vols. Erster Teil, Aadl-kynurensäure. Pp. iv+454. Zweiter Teil, Lab-zymogen. Pp. 415. (Leipzig: Verlag von Wilhelm Engelmann, 1910.) Price 22 marks.

THESE two volumes bear striking testimony to the enormous strides made during the last twenty years in agricultural chemistry. Only within very recent times has the need for a cyclopædia been felt; previously the chemist could always pull through if he possessed one of the larger analytical treatises and had access to a set of the *Jahresberichte* for agricultural chemistry. Rapid progress set in when the subject was emancipated from the analytical stage; when the chemist, instead of being confronted with an interminable succession of analyses of manures, feeding-stuffs, and soils, was free to study the numerous problems presented by the plant in its relation to the soil, on the one hand, and the animal on the other.

To the popular mind the agricultural chemist is still an analyst, and beyond doubt the analyst is more necessary than ever he was; but the distinction between the two is fast becoming as sharp as in pure chemistry. This process of segregation is going even further, and already men are specialising in the various branches of agricultural chemistry itself. Hence the need of reference books like the present volumes.

One of the features of the book is the treatment of laboratory operations. The ordinary methods are dealt with in some detail, there are numerous illustrations, and, where necessary, tables of figures. Even such minor but important processes as the recovery of platinum, silver, &c., from their residues find a place. In addition, a number of tests are given, and methods for finding whether nitrogen is present as an amide group, an amino-acid, or an ammonium salt. Although these are probably the fullest articles in the volumes they are rather restricted in their scope, attention is devoted almost exclusively to German methods, little space being given to those in use elsewhere. In several instances the book suffers in consequence. Thus we find the methods for the mechanical analysis of soils are very incomplete; the separations are carried only far enough to include material more than 0·2 mm. in diameter, all below this limit being grouped together as fine sand, &c. This is very unfortunate, because it is now known that the finer fractions—those falling between 0·2 and 0·04 mm., between 0·04 and 0·01 mm., between 0·01 and 0·002 mm., and below 0·002 mm.—really play a controlling part in soil fertility; indeed, no soil analysis can be fully interpreted without knowing them.

The book is, however, more than a laboratory manual, and space is found for some of the great generalisations and theories that have played a part in the development of the subject. The treatment is all too brief, especially when one remembers the importance rightly attached in Germany to theoretical considerations. Liebig's famous "law of the minimum" is stated, but its modern developments are not mentioned. "The growth of the plant is governed by the quantity in the soil of that food constituent which is present in the smallest amount." This generalisation has proved of great value in agriculture, but it is now merged in the wider conception of limiting factors, which we should like to have seen discussed in the book. It is now recognised that certain requirements must be fulfilled before plants will grow well—there must be ample water, air, warmth, food, light, and no injurious substance must be present. Any increase in one of these factors may lead to an increased crop production, but the increase is soon limited by the insufficiency of some one or more of the other necessary factors. If all are increased, the limit is finally set by the plant itself. In general, however, modern hypotheses are not given; we have been unable to find any mention of the well-known toxin-excretion theory of Whitney, which supposes that infertility arises through the excretion of toxic substances by plant roots. Whether it ultimately turns out correct or not, this theory has led to so much investigation that it deserved a place.

A critic could easily point out much more that has been omitted. But he would find it difficult to see how it could be otherwise within the limits of two

volumes, the available space of which has been still further reduced by the numerous good illustrations the editor gives us. There are, however, cases where the really important information is not given. Take, for instance, the note on *Molinia coerulea*. We are told that it has the power of absorbing considerable quantities of the salts of heavy metals, and a case is quoted where the ash contained 2·041 per cent. of lead oxide, 0·266 per cent. of copper oxide, and 0·265 per cent. of zinc oxide; further, we are told that it is regarded as a bad pasture grass. Now molinia is a weed and not a cultivated crop, and the things the chemist wants to know about it are these: What soil conditions does the presence of molinia indicate? and has molinia ever been observed to produce any ill-effect on animals? if so, what is the harmful constituent? Information could have been given on the first point that would have been valuable, for molinia is a useful "indicator" plant. Again, we are given analyses of animal excreta, but no mention is made of the fact that the composition is very variable, nor are we told whether the figures represent means of many analyses or only one or two determinations.

A more serious defect, however, is the omission of references. The student is rarely told where to go for fuller information, and it is practically impossible for him to check the data given in the article unless he knows his way about the literature of the subject. It is inevitable that dictionary notes should be short and should omit much; their great value ought to be the guidance they afford to the man who wants to learn more. But even with this defect the volumes are very useful, and will prove a distinct acquisition to the agricultural chemist.

E. J. RUSSELL.

RADIO-CHEMISTRY.

Radiochemistry. By A. T. Cameron. Pp. viii + 174. (London: J. M. Dent and Sons, Ltd., 1910.) Price 2*s*. 6*d*. net.

THIS book purports to be an "exact account of our present knowledge of the chemical properties of the radioactive substances and their chemical effects," and in the preface much stress is laid on the "accuracy" of the facts and theories here presented. It is further stated that the subject is "treated from a chemical standpoint," while "the physical side is introduced only so far as is necessary to explain the special experimental methods." As to how well the author has attained the latter object can be best judged from two examples, one a description (quite incorrectly asserted to be "that in Rutherford's 'Radioactivity,' p. 86") of a Wilson type of electroscope (p. 10), where, in addition to a very extraordinary earth connection, the movement of the aluminium leaf is observed by a "telescope" which "carries a scale," a distinctly inconvenient and unusual arrangement; and the other a description of a Dolszalek electrometer (p. 13) having "one pair of quadrants connected to earth, the other to an insulated metallic plate facing a second which carries the radioactive matter to be tested." "Through action similar to that in the case of an electroscope an electric stress is set up between the two pairs," and "the needle, previously charged to a very high potential, is repelled from one pair of electrodes towards the other"!

The chapter on the "Classification of the Radioactive Elements—their Physical and Chemical Properties" might be expected to justify the title chosen for the book, but it is disappointing to an extreme extent; the chemical properties of uranium, for example, being dismissed with the bare statement that "it belongs to the iron group of elements and is precipitated by ammonium carbonate." The discussion of the identification of ionium is quite misleading, and the account of the chemical properties of the other radio-elements of a very superficial character. The statement that thorium "occurs chiefly in Ceylon" is certainly surprising. It is doubtful whether anyone not already somewhat familiar with the subject could separate or identify a single radio-element from the directions which are given.

Errors and misleading statements are not uncommon. Thus (p. 17) the simple exponential equation $I_t = I_0 e^{-\lambda t}$ is given in an inverted and incorrect form, which again appears later (p. 90). Further examples are the statements (pp. 56, 141) that radiothorium "is precipitated with barium," "resembles radium in every respect," and has an activity "several hundred thousand times that of radium"; that in the separation of uranium X by treatment with a mixture of ether and water (p. 39) "the ether layer contains most of the photographic or β-ray activity"; that the active deposit from the radium emanation (p. 51) "decays to half value in twenty-eight minutes, but the decay curve is very irregular"; and that "the actinium products have all extremely short lives so that the maximum activity is quickly reached (p. 56). The mention of the "decay curve of a *radioactive child*" (p. 17) certainly suggests the most gruesome possibilities!

B. B. BOLTWOOD.

EGYPTOLOGICAL RESEARCHES.

Egyptological Researches. By W. Max Müller. Vol. ii., Results of a Journey in 1909. Pp. v + 188 + 47 plates. (Washington: Carnegie Institution, 1910.)

FOUR years ago Herr W. M. Müller, now of Philadelphia, published a first volume of "Egyptological Researches," brought out at the expense of the Carnegie Institution of Washington, which had borne the expense of the journey to Egypt in 1904 the results of which were thus published by Herr Müller. In 1906 Herr Müller undertook a second journey to Egypt, and now publishes a second volume of these "Researches."

Herr Müller's chief aim on both journeys was to pick up as much as possible of the hitherto unedited and badly edited historical material which still is to be found in the inscriptions of Thebes, notwithstanding the labours of many Egyptologists. In his first volume he published in colour the extant remains of the famous pictures of Minoan Cretan ambassadors in the tomb of Senmut, the prime minister of Queen Hatshepsut, which are so important to the Greek archæologists. These pictures had already been pub-

lished long ago, in colour, by the French scholar Prisse d'Avennes. The tomb was then lost sight of until re-discovered by Prof. Newberry some years ago. No new publication of the tomb was made, though it is understood that Mr. Howard Carter made a fine coloured drawing for one, until Mr. H. R. Hall published some rough sketches, correcting Prisse's errors, in the "Annual of the British School at Athens" (vol. viii., pp. 172–3), following this up with a photograph of the whole important scene, in the same publication (vol. x., p. 154). Herr Müller then followed with a coloured reproduction on a larger scale in the first volume of "Egyptological Researches." This is very useful, though naturally it is not likely to be so good as Mr. Carter's drawing, which so unaccountably remains unpublished still. Herr Müller's colours were too crude.

In the present volume of "Researches," Herr Müller provides us with similar (and too crudely) coloured reproductions of the scenes painted on the walls of the tomb of Menkheperrā-senb, which also include representations of Minoans. The figures and features of the Cretan ambassadors to the court of Thothmes III. are here represented more clearly than in the tomb of Senmut, though the vases which they carry are not so well or so carefully portrayed. The best of all these representations is probably that in the tomb of Puamra, also at Thebes, which will, we hope, shortly be published with a coloured drawing made on the spot by a most competent artist, Mr. de Garis Davies.

Herr Müller publishes a great many other scenes from tombs and temples at Thebes, with explanations, which are naturally comprehensible only to Egyptological experts, though the subjects of which they treat are of great interest to the general historian, anthropologist, and archæologist. Herr Müller is too technical, is insufficiently explicit, and assumes too much knowledge on the part of his readers, since he is not now writing exclusively for the edification of his *engeren Fachgenossen*. His style also is too notebooky, too much mere jotting down, too *staccato*, though we must congratulate him on his command of English. It is true that he would have done well had he submitted his text for revision to an American colleague before publication, as there remain in it many clumsy phrases and strong Teutonisms. Such forms as "Merenptahtext," "Kahunpapyrus," are German, not English; we always insert a hyphen between the elements of such combinations. We may also quote a very weird phrase on p. 76, "not doest thou look at the mountains" for "thou dost not look at the mountains"; and the quaintly unintelligible sentence, "strange that Duemichen's uncritical credulity toward the plays of the latest time has been revived recently!" (p. 39), needs an Egyptologist with a knowledge of German as interpreter. Herr Müller is not talking about *Schauspiele*, as one might suppose. It is not clear to us what, or rather whom, he is here talking about, or rather, at; this writer seems somewhat given to cryptic "digs" at other men of science, which are apt to fall flat if incomprehensibly phrased!

Though the coloured plates might sometimes be more carefully printed (*e.g.* plate xii. in our copy), the photographic illustrations of the battle-scenes of Rameses II. at Karnak and Luxor are very fine, and the whole book reflects credit on its author and great credit on the Carnegie Institution.

UNPROGRESSIVE PETROLOGY.

Les Roches et leurs Éléments minéralogiques; Descriptions, Analyses Microscopiques, Structures, Gisements. By Ed. Jannettaz. Fourth edition, revised and enlarged. Pp. 704. (Paris: A. Hermann et Fils, 1910.) Price 8 francs.

MOST of those who were students of petrology in the later years of the nineteenth century were familiar with a modest volume, published by the late M. Jannettaz, under the title of "Les Roches." It had a special interest for English readers, as it enabled them to realise the lines on which the teaching of the subject was carried on in France. Amongst other matters, it comprised a readable account of the Haüy system of crystal notation long forgotten in this country, a short section on crystal optics, and a description of the chief rock-forming minerals and rock types.

It was considerably enlarged but hardly improved in the third edition published, after a long interval, in 1900, and still to be found in some of our reference libraries. More than a hundred pages are devoted to the optical characters of crystals, but the treatment is at once ambitious and incomplete, and whatever merits it possesses are obscured by the innumerable misprints and blunders, which are found in its pages, and must render them almost unintelligible to anyone who resorts to them for information. It is difficult, indeed, to believe that the proofs ever passed through the author's hands. We find, for instance, "$E^2/2$" for E^2/α^2, "$\cos^2 \pi t/T$" for $\cos 2\pi t/T$, and are startled to learn that "$\cos r=2$." The description of the rock-forming minerals is expanded into a treatise on the entire mineral kingdom and little used terms like newjanskite and sysserskite are included, while we look in vain for the refractive indices and birefringence of the commoner rock-forming minerals. The classification and nomenclature of the igneous rocks is open to serious criticism, and is based to a considerable extent on chronological principles, for we are told:—"Les géologues répugneront longtemps à confondre sous le même nom des roches qui sont arrivées au jour à des époques si différentes."

It would have been a work of supererogation to enumerate the defects of a book published ten years ago, if the fourth edition, which bears the date 1910, had not proved on careful examination to be identical with its predecessor. It is not merely that the advances of science in the interval have been ignored, but that every inaccuracy in the third edition, however obvious to the most casual reader, is faithfully reproduced. A hiatus in a reference, represented by a line of points, is left still unfilled, and even the table of errata, which corrected only a fraction of the misprints, and added more of its own, remains word for word the same. Yet we are told that this is a new edition, "revue et augmentée." The revision consists,

it would seem, in the substitution of a fresh title-page, with a later date and the name of a different publisher, and the enlargement in the addition of eight reproductions of photographs, some at least of which do not appear for the first time.

Any value the book once possessed has now been greatly diminished by simple lapse of time, and the appearance of this reprint under the false colours of another edition can only be regarded as a breach of faith on the part of those who are responsible for it.

ELEMENTARY MATHEMATICS.

(1) *The Public School Geometry.* By F. J. W. Whipple. Pp. xii+154. (London: J. M. Dent and Sons, Ltd., 1910.) Price 2*s.* 6*d.* net.

(2) *The Student's Matriculation Geometry.* By S. Gangopádhyáya. Second edition, revised and improved. Pp. xviii+348. (Calcutta: The Students' Library, n.d.) Price 1.4 rupees.

(3) *First Stage Mathematics.* Edited by W. Briggs. Pp. vii+194. (London: W. B. Clive, 1910.) Price 2*s.*

(4) *Second Stage Mathematics (with Modern Geometry).* Edited by W. Briggs. Pp. viii+128+102+186+14 (answers)+21 (exam. papers). (London: W. B. Clive, 1910.) Price 3*s.* 6*d.*

(5) *Conic Sections.* By S. Gangopádhyáya. Pp. viii+97. (Calcutta: The Students' Library, 1909.) Price 8 annas.

(6) *Public School Arithmetic.* By W. M. Baker and A. A. Bourne. Pp. xii+386+2. (London: G. Bell and Sons, Ltd., 1910.) Price, with answers, 4*s.* 6*d.*, without answers, 3*s.* 6*d.*

(7) *A School Algebra.* By H. S. Hall. Part I. Pp. xi+299+xxxvii. (London: Macmillan and Co., Ltd., 1910.) Price 2*s.* 6*d.*

(8) *Elements of Algebra.* By A. Schultze. Pp. xii+309. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 4*s.* 6*d.*

(9) *The Theory of Elementary Trigonometry.* By Prof. D. K. Picken. Pp. vii+48. (Wellington, N.Z., and London: Whitcombe and Tombs, Ltd., 1910.) Price 2*s.* 6*d.* net.

(1) FREE use is made in this volume of inductive methods in establishing the fundamental facts of geometry—the conditions for congruency and parallelism. The opening chapters deal with the measurement of lines and angles and with a few simple constructions. Then follow the elementary properties of the triangle and parallelogram, the usual theorems on inequalities, and a short account of areas. The principles of similar figures are then discussed, and are employed to prove Pythagoras's theorem. And the book closes with the angle and metrical properties of the circle. The author has succeeded in giving in a very concise form a useful summary of the subject-matter of the first six books of Euclid. We regret the introduction of two new terms—new at least so far as elementary text-books are concerned—the use of the word "stretch" for a segment of a straight line, and of the word "cognate" for "corresponding"; while the definition of π on p. 16 is not merely misleading but is incorrect. It is most important that the student should understand that π is a pure number and not an angle. There are a very large number of numerical examples, but most teachers will consider the supply of riders inadequate.

(2) The plan of this book conforms very closely to the syllabus for the matriculation examination at Calcutta, which is practically identical with the Cambridge schedule for the previous examination, the section on proportion being omitted. While due attention is paid to experimental and numerical work, the author has very wisely given chief place to the theoretical developments of the subject. We welcome the presence of a certain number of historical allusions, which might with advantage be increased in a future edition. Those who use this book will find that it answers with uniform success the purpose for which it was written. From its general workmanship it is evident that this volume comes from the hand of an experienced teacher.

(3 and 4) The two parts of this treatise are designed to meet the requirements of the Board of Education examinations in first- and second-stage mathematics. The first part therefore contains the substance of Euclid, book i., and the elementary algebraic processes as far as simultaneous and literal equations. In the second part will be found the substance of Euclid, books ii.–iv., the section on algebra including quadratics, indices, and proportion; the remainder of the volume provides the requisite course of trigonometry up to and including the solution of triangles by logarithms. We have no hesitation in saying that this text-book is admirably suited to the needs of those students who are reading by themselves for this examination, or any other of a similar character. The authors have made good use of their experience in anticipating the nature of the difficulties which the reader is likely to meet with, and in resolving them in a lucid and accurate fashion; and further, what is equally valuable, attention is directed to many points of logical importance which a student is apt to overlook, if working without any supervision. There is a rich supply of well-graded examples and a large number of examination papers, which furnish the student with opportunities for testing his progress.

(5) This book falls into three sections. There is first an introduction containing several preliminary lemmas, together with a few remarks of a general character bearing on geometrical procedure, the second part relates to the parabola, and the concluding chapter to the ellipse. The author has not aimed at giving a complete account of the geometrical properties of conics, but rather a selection of the more useful theorems, his objective being the syllabus for the Calcutta intermediate examination. This leads to some regrettable omissions; there is, for example, no mention of the auxiliary or director circle. Each proposition is followed by a number of simple applications and a few riders of a somewhat harder type are given at the end of each chapter. The book will serve as an admirable introduction to the subject. Among other good features we note the introduction of analysis at several stages, which is calculated to enlarge the outlook of the reader.

(6) There is little that differentiates this from the other numerous text-books on arithmetic which have appeared during the last few years. The supply of examples for oral and written purposes is plentiful, and a large number of test papers are provided. Although it is probable that those who use this book will find it thoroughly satisfactory, yet we do not consider that it marks any real advance on other recent publications of a similar nature.

(7) The present work is far more than a mere revision of Hall and Knight's "Elementary Algebra." Although some of the features of this book, first published twenty-five years ago, have been retained, yet the organic changes in method of late years demand alterations so considerable that the volume before us is to all intents and purposes a new book. It is marked throughout by the same clearness of style and thoroughness of treatment which characterised the author's earlier work. Graphical methods are employed, but it is satisfactory to note that they have been kept within reasonable limits. The tendency to allow it to expand into an elementary course of analytical geometry is a fatal error, for it overlooks the fact that the student is not sufficiently mature at that stage to be able to appreciate the significance of the theoretical aspect of the subject. We hope that this book will be widely used, for it is both sound and comprehensive. Part i. carries the reader as far as simultaneous quadratics. We understand that part ii. is to be published very shortly.

(8) It has often been pointed out that one significant feature of the influence of examining bodies on the educational curriculum is the tendency to standardise into distinct types, and to collect under separate headings, applications of general principles which the student should be so educated as to work out for himself, when required to do so. The old-fashioned text-books on arithmetic bear emphatic witness to this deplorable result; and it is of some importance to consider whether works on algebra are not similarly affected. This is not the place, however, to develop this theme; but in England it is satisfactory to note that the principles which have actuated those educational bodies which are responsible for the leaving certificate and Army qualifying examinations do much to minimise a very real danger. The author of the present volume attempts to meet the sitaution by focussing attention on the central facts and encouraging the reader to make the requisite applications for himself. By avoiding multiplication of detail, he is able to cover a wider range and prepare the student for more advanced work, in a shorter time than would otherwise be possible, without any sacrifice of principle. The explanatory matter is both full and clear, and there are many useful hints, particularly in connection with the solution of problems. We are, however, inclined to regret that the method of undetermined coefficients is omitted, and that the chapter on the binomial theorem is not prefaced by some quite short account of permutations and combinations, treated numerically. There is at the end of the book a useful collection of more than a thousand examples for revision purposes, which are rather harder than those given in the text. The author has done his work well, and his book deserves a good reception.

(9) There is much that is novel in the plan of this book. Broadly speaking, there are two types of text-books. In one the subject is presented in as simple and elementary a fashion as possible, with no attempt at investigating the fundamental axioms and principles on which the theory is based, and in the other a substantial knowledge of the actual analytical results is assumed and attention is concentrated on the formal concepts. Both of these are beneficial, when properly used. In the study of elliptic functions, for example, it is customary to approach the subject by considering such cases of integration which do not lead to any known elementary function; but when the student has acquired a knowledge of the general results, it is very valuable to start again and take as the base the theory of a doubly-periodic function. Prof. Picken has set himself the task of compiling a book for those who are actually starting trigonometry during their university course. His contention is that such students will have attained a maturity of mind which will be fully capable of appreciating the theoretical principles of this subject, and his object is therefore to supplement the ordinary school treatises which refer almost exclusively to numerical applications. We have little doubt that the class of students the author has in view will materially benefit by his work, which, although brief, is both lucid and scholarly.

OUR BOOK SHELF.

Milch und Molkereiprodukte, ihre Eigenschaften, Zusammensetzung und Gewinnung. By Dr. Paul Sommerfeld. Pp. 140. (Leipzig: Quelle and Meyer, 1910.) Price 1.25 marks.

THIS little book forms one of a series entitled "Wissenschaft und Bildung," the object of which is to present the intelligent reader with brief accounts of particular subjects. It is rather more technical than our own popular books of the same size would be, and naturally it lacks the completeness of a monograph. But it would prove distinctly useful for a large class of readers, including students and lecturers at agricultural colleges, and farmers who take more than a commercial interest in their work. It seems, indeed, to be a very useful method of dealing with a complex subject like agriculture.

The first chapter describes the constituents of milk, giving a clear and concise account of the protein, carbohydrates, fats, and mineral matter present, and then follows a section on the characteristics of milk from various animals. In discussing human milk some interesting statistics are given that show how difficult it is to supply any artificial food to infants that shall take the place of the mother's milk. In Berlin during 1905 the total number of infants dying under twelve months of age was 10,170. The method of feeding 7738 of these was known; 7064 had been fed on cow's milk and only 674 on human milk. The figures for other years are similar.

The chapter devoted to the bacteriology of milk is subdivided into three portions, dealing respectively with fermentation organisms, with organisms producing disease in man, and with organisms producing taints or defects in milk, such as ropiness. As all this is compressed into less than twenty pages the treatment is necessarily very brief.

Lastly, there comes a well-illustrated section on milk products and the methods of working them up for market. So important is cleanliness in working that several pictures are given of modern cow-sheds built on the best possible principles; in one, indeed, the cowman is shown cleansing the cow with a special vacuum cleaner! This section will probably prove most interesting to English readers, as it gives fairly full outlines of the German factory methods.

A few misprints are inevitable, but how did this wonderful piece of Greek on p. 12 pass the proof-reader "kohlenhydrate (von λγδορ hydor = griechisch wasser)"? E. J. R.

Theoretical Mechanics. By P. F. Smith and W. R. Longley. (Ginn.) Price 10s. 6d.

UNTIL the student has acquired a certain manipulative dexterity, it is impossible to preserve a proper continuity of thought in the development of the application of infinitesimal theory of mechanics or any other applied science. The authors are therefore justified in assuming that the reader comes to this subject equipped with a thorough working knowledge of the methods of the calculus. In the opening chapter a good account is given of the means for obtaining centres of gravity and moments of inertia of plane and solid figures; no mention is made, however, of the application of orthogonal projection to the theory of the centroid. Chapters ii.–iv. deal with the principles of rectilinear and curvilinear motion in a most attractive fashion; as an example, the motion typified by $x = a \cos kt$ is considered, the equation $d^2x/dt^2 = -k^2x$ is deduced, and the properties of harmonic motion are then obtained in a simple fashion; a similar treatment is applied to damped vibrations. This is followed by an exposition of work, energy, and impulse. Chapters vi.–ix. discuss the motion of a particle under constant forces, central forces, in a harmonic field, and against a resisting medium. The volume closes with a brief account of the equations of rigid dynamics and the principles of equilibrium of a coplanar system of forces with special reference to the catenary.

The examples, which are very numerous, are mainly numerical and practical, and so chosen as to require a minimum of analytical power. This feature renders the book eminently suitable for the senior divisions of secondary schools, where the true understanding of the ideas of mechanics is the chief object. It is to be regretted that practically no English text-book has treated the subject on these lines, a fact which is due mainly to the action of the universities in excluding the simpler applications of particle and rigid dynamics from their entrance scholarship examinations. We hope that the time is not far distant when this restriction will be removed.

The Anatomy of the Honey Bee. By R. E. Snodgrass. (U.S. Department of Agriculture, Bureau of Entomology, Technical Series, No. 18.) Pp. 162. (Washington: 1910.)

IN this modest pamphlet the author has given to entomologists an original, trustworthy, and excellently illustrated account of the structure of the honey bee, and another instance has been furnished of the scientific thoroughness that characterises the publications of the United States Department of Agriculture. Many volumes have been written on the honey bee, yet no surprise can be felt that Mr. Snodgrass has been able to add new points to our knowledge and to correct errors in the work of his predecessors. A feature of value to the serious student is the general survey of the external structure of a typical insect which the author has wisely given as an introduction to his account of the highly specialised modifications to be found in the bee. He expresses scepticism as to certain positive statements that have been made on controverted details of physiology and reproduction; for example, "concerning the origin of the royal jelly or of any of the larval food paste . . . we do not know anything about it." There is a present-day tendency unduly to disparage the results obtained by former workers, and such a statement will strike many readers as extreme. Mr. Snodgrass's scepticism as to the parthenogenetic nature of "drone" eggs seems also unwarranted after the support which Weismann's researches, published ten years ago, afford to the generally accepted view. G. H. C.

Practical Physiological Chemistry: a Book designed for Use in Courses in Practical Physiological Chemistry in Schools of Medicine and of Science. By Philip B. Hawk. Third edition, revised and enlarged. Pp. xviii + 440. (London: J. and A. Churchill, 1910.) Price 16s. net

BOTH the first and second editions of Prof. Hawk's volume have been reviewed in these columns; the former in our issue of July 18, 1907 (vol. lxxvi., p. 268), and the latter in that of July 15, 1909 (vol. lxxxi., p. 67). The present edition has been brought up to date by the insertion of various additions and corrections, as well as by the inclusion of a number of qualitative tests and quantitative methods.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Simulium Flies and Pellagra.

IN reference to Mr. Shelford's letter in NATURE of November 10, in which he directs attention to the difficulties in controlling and eradicating the flies of the genus Simulium, known generally as sand flies and black flies, it may be of interest to direct attention to certain experiments carried out in New Hampshire by Dr. C. M. Weed and Prof. E. Dwight Sanderson and their assistants in the control of these insects. The southern buffalo gnat, *Simulium pecuarum*, Riley, which attacks and kills many animals, such as horses, cattle, mules, sheep, poultry, dogs, &c., is well known. In certain parts of the United States, but especially in Canada, "black flies," generally *S. hirtipes*, Fries, and *S. venustum*, Say, make life far more intolerable than mosquitoes, and they are specially annoying when they occur in such resorts as the White Mountains.

In 1903 Dr. Weed and his assistant, Mr. A. F. Conradi, showed that the Simulium larvæ, although they live on the stones in running water, could be killed by the application of Phinotas oil. The destruction was so complete that the flies were practically eradicated in the locality in which the experiments were carried out (see "Experiments in Destroying Black Flies," Bull. No. 112 New Hampshire Agric. Exp. Sta., 1904). A floating oil such as kerosene is manifestly useless for the destruction of larvæ having such habits as Simulium, and the efficacy of Phinotas oil is due to the fact that it has the property of sinking to the bottom in water, thus destroying the larvæ which are stationary on the stones. Further experiments have been carried on more recently in the White Mountains by Prof. E. Dwight Sanderson, and he also found that Phinotas oil applied to the running streams was effectual in the destruction of the Simulium larvæ (see "Controlling the Black Fly in the White Mountains," E. D. Sanderson, *Journal Economic Entomology*, vol. iii., p. 27, 1910). There still remains, however, much experimental work to be done with regard to the effect of the oil upon the fish, the details of the life-histories of the species of Simulium, and the practical methods to be used in applying the oil.

If Dr. Sanbon's results are confirmed, and the Simulium

theory is certain to form the basis of a careful and complete series of investigations, not only in Europe, but also in those regions in Africa and America where pellagra also occurs, these experiments and results on the destruction of the Simulium larvæ will be of no little practical importance in the prophylaxis of the disease, whether a definite pathogenic organism is discovered, or the case proves to be analogous to that of Stegomyia or yellow fever.

C. Gordon Hewitt.

Division of Entomology, Ottawa, November 21.

The Song of the Siamang Gibbon.

The Zoological Society has recently received on loan an almost adult example of the siamang (*Symphalangus syndactylus*); and since I can find no adequate description of the voice of this ape in the books I have consulted, I think the following description may be interesting to readers of Nature.

The siamang differs from all other gibbons in having a pair of laryngeal vocal sacs visible externally on the throat as an undivided pouch of loose skin. When the animal is in full song the pouch becomes inflated into an immense oblate spheroid much wider from side to side than from above downwards, and comparable in size to the entire head of the gibbon. A feeble imitation can be made of the booming that comes from this pouch by uttering a guttural monosyllabic "*ooo*" with cheeks inflated and lips compressed. It is not unlike the sound produced by a large bubble of air bursting on the surface of water confined in a narrow space like a rain-water pipe. In addition to this there are two very distinct cries apparently quite independent of the vocal sac and uttered with the mouth open. One is a shrill, piercing bark, like the monosyllable "*haow*," cut off sharply by the abrupt closing of the lips. The other is a prolonged, unearthly wailing shriek—"*ahh—o*"—resembling more than any familiar sound to which I can compare it the "*miaou*" of a cat multiplied ten times in volume. It starts on a high pitched note with the mouth widely astretch, and gradually descends the scale as the jaws are closed. There are two variations of this shriek, one being a note or two higher and more piercing than the other.

The song usually begins with a low and gentle booming punctuated by an occasional staccato bark. As the excitement rises the ape starts to move, and swings round the cage barking vigorously and repeatedly, and now and again uttering the wailing shriek, the loud booming from the now fully expanded vocal sac going on all the while like a resonant bass accompaniment. The noise is deafening and terrific, and I shall not easily forget the consternation of the chimpanzees and the look of mild surprise that pervaded the usually expressionless faces of the orang-utans when they heard it for the first time in the apes' house.

The voices of Mammalia have never, I believe, been carefully studied and compared; yet they are worthy of the closest attention as a criterion of specific relationships. The cry of the siamang, for instance, is quite different from that of the Hainan, Hoolock, and Wau-wau gibbons, and each of these species has its characteristic song. I have elsewhere pointed out that the bray of Grévy's zebra betrays pronounced asinine affinities, and equally forcibly attests remoteness of kinship between that species and the quaggine Equidæ; that the likeness between the roar of the lion and the tiger on one hand and of the jaguar and the leopard on the other confirms the conclusion that these species are respectively closely allied, and that these four great cats form, with the probable inclusion of the ounce, a special group of Felis characterised by a roaring voice correlated with a peculiarly modified hyoidean apparatus; that the friendly purr practised by the puma, cheetah, caracal, common cat, and other species which, be it noted, never roar, distinguishes them from lions, tigers, and leopards, which never purr. To the casual observer the Cape hunting dog (Lycaon) is more like a hyæna than a wolf, but the moment he barks and growls it is needless to look at his teeth and skull to detect his cousinship to Canis; and I have recently noticed identity in all essential respects between the raucous growl of a frightened cervine wallaroo (Macropus) and that of a nervous Tasmanian wolf (Thylacinus). In this last instance we have vocal likeness associated with deep-seated ordinal resemblances, and apparently persisting despite great divergences in other structural features and in habits.

Zoological Society.

R. I. Pocock.

On the Simultaneity of "Abruptly-beginning" Magnetic Storms.

In the first number of *Terrestrial Magnetism and Atmospheric Electricity* for the present year, Dr. Bauer has written two papers, in which he believes he can prove the following (p. 20):—

"Magnetic storms do not begin at precisely the same instant all over the earth. The abruptly beginning ones, in which the effects are in general small, are propagated over the earth more often eastwardly, though also at times westwardly, at a speed of about 7000 miles per minute, so that a complete circuit of the earth would be made in $3\frac{1}{2}$ or 4 minutes."

Dr. Bauer bases this result upon an investigation of two magnetic storms of Birkeland's "positive equatorial" type, namely, the storms of May 8, 1902, and January 26, 1903. In the latter he makes use of a table in Birkeland's "The Norwegian Aurora Polaris Expedition, 1902–3."

In the following number Dr. Faris made a more thorough investigation of this circumstance, taking fifteen different abruptly beginning storms, recorded at the Coast and Geodetic Survey magnetic observatories, in which he considers that he found Dr. Bauer's result confirmed.

Upon this foundation Bauer then develops the "Ionic Theory of Magnetic Disturbances" (*loc. cit.*, p. 111), of which the principal advantage over Birkeland's corpuscular theory is supposed to consist in the being able to give a natural explanation to time differences such as these, which Birkeland's theory, in his opinion, cannot do.

Notices of these papers appeared in Nature of August 11.

As it appears that a number of the perturbations described by Dr. Faris are some that I studied last summer when making an investigation of magnetic equatorial storms at the magnetic observatory in Potsdam, a comparison may be of some interest. I determined also the time of the commencement of a number of positive equatorial storms as accurately as possible for another purpose, and without any knowledge of Dr. Faris's work, so that the measuring of the time was entirely independent of it, a circumstance which may be worthy of note.

It may be remarked with regard to the exactness with which the time can be determined by the Potsdam curves that the length of an hour upon the magnetograms is about 20 mm., and that thus one minute answers to about $\frac{1}{3}$ mm. If we then take into consideration all the errors that may creep in because the curves, the time-marks, and the points considered are not so sharply defined as might be wished, and further all the errors that may be due to changes in the paper in developing, owing to the fact that the paper has perhaps not laid quite straight on the roller, &c., it will be evident that where there are no exact automatic time-marks upon the curve itself, one minute will at any rate be the *lowest* limit for the accuracy that under favourable conditions can be counted upon.

There might very easily be an uncertainty of several minutes if, for instance, the base-line is not exactly straight, but is slightly curved, if the parallax cannot be determined exactly, and so forth. Unfortunately, neither Dr. Bauer nor Dr. Faris has stated anything as to how the time in the various cases can be given exactly, a point upon which, it would be thought, it was highly important to be clear.

In the equatorial storms that I have studied, and especially those that are also found in Dr. Faris's Table I. (*loc. cit.*, p. 101), the point at which they commenced is especially clear in H. The deflections in D and Z, on the other hand, are very slight, and in consequence the beginning there is far less clearly defined.

It is therefore the beginning in H that is especially suitable for employment in a comparison such as this, and this was what I especially investigated. It will *a priori* be perceived that the results obtained by employing the other two components must be far more uncertain. In the table below I have compared the means of the values found by Faris for the five American stations that he has considered with those I measured out by the aid of the

Potsdam curves. Finally, I have also given the difference (d_r) between the greatest and the smallest time given in Faris's Table I. for the commencement in H at the American stations (Greenwich mean time is employed).

Date	America h. m.	Potsdam h. m.	Diff. m.	d_r m.
1906, July 29	19 56·12	19 57	−0·88	3·7
1907, ,, 10	14 22·92	14 22·5	+0·42	3·8
,, Oct. 13	7 42·36	7 42·5	−0·14	3·9
1908, Sept. 11	7 20·82	7 20·3	+0·52	1·3
,, ,, 28	8 42·00	8 42	0·00	2·3
,, ,, 29	1 31·68	1 31·8	−0·12	3·4
Mean			−0·03	
Mean of numerical values			0·35	3·07

It will be observed that all the differences are considerably below the error-limit which, according to the above, must be reckoned upon, and the difference is as frequently one way as the other.

These figures seem to me to show clearly that in these cases the magnetic impulse occurs, at any rate, very nearly *simultaneously*; in any case there cannot be time-differences of such a magnitude as in Dr. Faris's opinion there are—for July 10, 1907, he even assumes that the storm would take 11·6 minutes to encircle the earth. Further, we see that the *greatest* difference between Potsdam and the mean of the American stations, 0·88m., is only about two-thirds of the *smallest* difference, d_r, between the times at the American stations, 1·3m. This circumstance, and the fact that the relation between the numerical means of these time-differences is as 0·35 : 3·07, would seem distinctly enough to show that the great time-differences observed by Dr. Faris can only be due to inaccuracy in the determination of the time, and that the error-limit must be considerable.

Further, if we consider the foundation that Dr. Bauer has employed for the determination of the rate of propagation in the case of the storm of January 26, 1903, it must, I think, be deemed as weak and uncertain as the above-mentioned, which I was able to control. Birkeland, in speaking of the table employed (*loc. cit.*, p. 63), says:—

"The table shows that the time varies so little with the geographical position that it would be premature to draw conclusions from it. The slight differences may be ascribed to inaccuracies in the determinations of time on the magnetograms; for we see that if a difference in time for a certain point appears between two places, this difference is maintained for all the points, a circumstance which seems best to be explained by an inaccuracy in the statement of the time. We may conclude from this that the serrations appear simultaneously, or rather, the differences in time are less than the amount that can be detected by these registerings. . . . The above question, which is of great importance, cannot be definitely decided until we are in possession of rapid registerings."

Bauer holds, however, that by taking groups of means he can demonstrate, clearly and surely, time-differences that would prove that the cause of the perturbation was transmitted eastwards at a rate of 6400 miles per minute.

I also last summer determined the commencement in H of this perturbation in Potsdam, and found the time to be 8h. 53m. Greenwich mean time. I moreover had the opportunity of going through the curves upon which Birkeland's table was based. From these it appeared that the times for the comparative correctness of which there was some guarantee were from the five following places:—Toronto, Kaafjord, Potsdam, Dehra Dun, and Bombay. As regards the other stations, it may be remarked that from Honolulu, Baldwin, and Cheltenham there were only received Indian-ink copies without hourly or two-hourly automatic time-marks. The parallax there could not be determined accurately, and the uncertainty in the time-determination must be considered to be relatively very great.

In the copy of the curve for San Fernando the base-line was a little curved. In that for Batavia the curve and the base-line were very faint; the parallax could not be determined with sufficient precision, and the time-marks were also rather indistinct. A new determination of the time of beginning which I have just made gives as the result 8h. 52·4m. for San Fernando and 8h. 52·8m. for Batavia. In the table these times are given as 8h. 54·3m. and 8h. 54·9m. respectively, a fact that demonstrates the uncertainty which attaches to these hours. At Christchurch it seems from the D and Z magnetograms as if the clock on that day was about 1·5 minutes too fast, so that the value 8h. 54·8m. given in the table probably should be reduced to about 8h. 53·3m. Further, the beginning of the base-line and the time-marks for the H curve were rather unsharp.

In addition, it may be remarked that the thickness of the curve at Bombay was considerable, about 0·9 mm., thus causing the commencement of the storm to be somewhat less clear; but, on the other hand, there were two-hourly automatic time-marks upon the curve itself, a circumstance which is of great importance in exact determinations of time.

If we now omit those that we already know to be very uncertain, we find the following times of beginning, putting Dehra Dun and Bombay together:—

Toronto	Kaafjord	Potsdam	Dehra Dun and Bombay	Diff.
8 52·6	52·6	53	53·3	0·7

Thus the greatest difference is considerably lower than the error-limit, and this would be still less if, as would indeed be best, we attach more weight to Dehra Dun, where the curve is exceedingly clear, than to Bombay. If we attach double the importance to the former, we find 53·1m. instead of 53·3m., and the difference will then be reduced to 0·5m.

It seems to me, also, that this last method, where the conditions are as they are here, must give a far more certain result than that which Bauer has employed.

The remaining characteristic points on the curve seem to me to be too indistinctly defined to allow of being employed in cases where the differences are as small as they are here.

Of the storm of May 8, 1902, I have no special observations that could serve to control Bauer's result. As regards Potsdam, however, I have a determination of its beginning in H, which I also made last summer before reading Bauer's paper. I found the time to be 11h. 58m. Greenwich mean time. Bauer, however, in his table gives it as 12h. 0m. It seems to me that this difference of two minutes is characteristic of the uncertainty that attaches to these statements. When Bauer finds that the weighted mean of all European stations is 11h. 58·24m., it looks as if my determination were the best. When such great differences can be found in the measurement of the same curve, and the Potsdam curves must, I suppose, be considered to be among the most trustworthy of all, how great must be the uncertainty that attaches to the others?

There seems from this, at any rate, to be by no means sufficient data to justify the conclusion that the magnetic storms are generally propagated round the earth in from about 3½ to 4 minutes, and the theory that Bauer mainly bases upon this we must be allowed to regard with corresponding scepticism.

But even if there are no such great time-displacements in these "abruptly beginning storms" as Bauer thinks, there is, of course, a possibility that small time-displacements might exist. This question, which is of such great importance for a full comprehension of the nature of the magnetic storms, can only, however, in my opinion, be solved, as Birkeland has suggested, by rapid registerings. It would be comparatively easy, moreover, to carry some such arrangement into effect by means of a number of stations—at least three—where a short or long period was registered continuously with *very sensitive apparatus* and with frequent and exact *automatic time-marks upon the curve itself*. This was the more easy of accomplishment from the fact that, for the solution of the present question, it was only necessary to register H in this manner. It would then be possible to obtain a sure foundation for reflections of the kind that Bauer makes in his last paper, reflections that, however interesting they may be, must, from what I can understand, be said to be in no small degree premature.

THE NEGRO IN THE NEW WORLD.[1]

WHEN, more than four centuries ago, the Portuguese obtained the sanction of the Roman Pontiff to engage in the African slave trade, and, some years later (Treaty of Tordesillas in 1494), Pope Alexander VI. assigned to Portugal the west coast of Africa and to Spain the New World (of which Portugal claimed Brazil, in accordance with the terms of the treaty), it could not have been foreseen that these acts were the first steps in the vastest anthropological experiment the world has ever witnessed, the effects of which for many ages to come are likely to confound and confuse the politics of the Americas. In Portugal itself the population has been transformed into Africanised mongrels, who at the present moment are busily engaged in casting out the representatives of the church that permitted them to begin the process of wholesale racial admixture four hundred years ago.

Negro slavery and the breeding of a mulatto population were by no means novel phenomena in 1494, for even then Egypt had been familiar with them for forty-five centuries; and, in less remote times, Arabia and western Asia, Greece, and Rome, Tunis and Morocco were only too familiar with the black slave and the half-caste. But the coincidence of the introduction of negro slaves into Portugal and the opening up of the New World by the two peninsular kingdoms makes the beginning of the sixteenth century—for the experiment of sending negroes to the West Indies began in 1516—a landmark in the history of the world.

Sir Harry Johnston has given a very complete history, without sparing us any of its appalling horrors, of the iniquitous traffic in black slaves, which ultimately led to the transference from one side of the globe to the other, and that a new continent, of a population (whose descendants now number twenty-five millions), which had grown up in the seclusion of the heart of Africa and had there become divergently specialised from the rest of mankind in bodily structure and mental and moral qualities. He has drawn a most graphic picture of how these negro people behaved in their new home, as they came into contact successively with the aboriginal Americans, and also the Iberians and the northern Europeans, who had settled in the New World.

Nothing has surprised the "lay" reviewers of this book in the newspaper press more than the revelation of the gross inhumanity of the representatives of the north European race (the English and the Dutch) towards the negro slave, when contrasted with the more generous behaviour of the Iberian and other Mediterranean peoples. Lamentable and indisputable as is the fact, the explanation is simple enough. The Mediterranean race was evolved and fashioned in an environment similar to, and perhaps in the same continent as, the African negro, and not only developed mental and moral qualities in many respects closely resembling those of the negro, which explains their mutual understanding the one of the other; but also the black and the brunet race had been in contact for many ages, had interbred, and had come to give equal rights to the offspring of mixed unions.

The blond people of the north, the representatives of a more austere civilisation, had nothing in common with the lazy, lascivious negro, and had no knowledge of or sympathy with him. Thus they came to treat him and his offspring, whether pure or mixed, as an inferior being of low intelligence and dirty habits.

When Mr. Roosevelt (at the time President of the United States) invited Sir Harry Johnston to undertake an investigation of the problems of the negro in the New World, he could not have chosen anyone to accomplish this task better fitted by personal knowledge and exceptionally wide experience of the negro in his native haunts.

Others may possibly have had equal opportunities

FIG. 1.—Type of the Virginian Negro of Slavery Days. From "The Negro in the New World."

of studying the negro in Africa, but certainly no one has made such excellent use of them as Sir Harry Johnston, who has already written eleven volumes on the subject.

With such an intimate knowledge of the essential negro, Sir Harry Johnston was well equipped for the examination of his behaviour under the influence of his altered surroundings in the New World.

In this book he has given us a detailed account, illustrated by maps and hundreds of excellent photographs, of the nature of each territory in the New World occupied by negroes or negroids, its commercial resources and social conditions, the place occupied in it by the black man, and especially the half-caste, and the degree of success and the possibilities for the

[1] "The Negro in the New World." By Sir Harry H. Johnston, G.C.M.G., K.C.B. Pp. xxix+499. (London: Methuen and Co., Ltd., 1910.) Price 21s. net.

future in ameliorating the lot and uplifting the coloured people, socially and morally.

Although no one is more fully aware than Sir Harry Johnston of the failings and moral weaknesses of the negro, he takes a very hopeful view—which many persons with a less intimate knowledge of the black man may think unreasonably sanguine—of his future, and especially of the hybrid's prospects, in the New World, provided only that he follows the example and teaching of his great and wise leader, Dr. Booker Washington, who "wants the negro to become the most industrious race in the United States" (p. 407), because only work will exhaust his energies and keep him out of mischief.

The book starts with a statement of Sir Harry Johnston's views on the negro's place in nature, which for the most part are well known to readers of his other books.

It is unfortunate, however, that on the very slender basis of the evidence afforded by the skeletons in the Grimaldi caves (see p. 26) he extends the habitat of

Fig. 2.—Type of Modern Negro; an electrical engineer trained at Tuskegee. From "The Negro in the New World."

the negro over half the continent of Europe and the whole of the British Isles!

It is not as a work of science, however, that this work, with its introductory *vulgarisation* of anthropology, is to be judged, but as a book of exceptional interest, and as the reasoned judgment of a man of wide experience on one of the most difficult sociological problems of the present time.

G. Elliot Smith.

GEOLOGICAL CHRONOLOGY.[1]

The vexed question of the age of the earth has passed through several distinct phases. Lyell and his contemporaries, accustomed to dwell on the extreme slowness of geological processes, considered themselves free to make unlimited "drafts on the bank of time"; but, since 1862, this position has been seriously challenged from the physical side. The chief argument brought against it was that, granting the globe to have cooled from a molten state, it would attain its assumed present thermal condition in a few scores of millions of years, only a fraction of which time would be available for the stratigraphical record. If the general body of geologists, influenced by the high authority of Lord Kelvin, have tried to adapt themselves to this narrow limitation, it has not been without reluctance, and some sturdy dissentients have refused any such coercion. To these, during the last few years, welcome support has come from unexpected quarters. The nebular hypothesis of the earth's origin, upon which the estimates of Kelvin and King were tacitly based, has been shaken by Moulton's calculations and other arguments put forward by Chamberlin. Moreover, the remarkable discoveries in the domain of radio-activity have compelled a reconsideration of the thermal state of the globe. Estimates of the earth's age deduced from its supposed rate of cooling clearly become futile if we have no good reason for believing that the earth is a cooling body. On the other hand, from the radio-active properties of various minerals Strutt has deduced geological ages liberal enough for the most extreme uniformitarian.

The debate concerning the age of the earth is thus no longer an issue between geologists and physicists, since the newer school of physics has declared on the side of the ampler chronology. Meanwhile, there has arisen within the body of geologists a formidable minority who contend, on geological grounds, for an estimate of geological time no more elastic than that imposed by the old argument from refrigeration. The discussion has followed two distinct lines, starting on one hand from the rate of accumulation of sediments, and on the other from the rate at which sodium is carried down by rivers into the sea. The interesting memoirs by Mr. Clarke and Dr. Becker, recently published by the Smithsonian Institution, deal mainly with the second mode of approaching the problem, but Becker offers also a revised estimate of the earth's age as calculated from the rate of cooling.

In 1899 Prof. Joly made estimates, first, of the total amount of sodium contained in the ocean, and, secondly, of the amount annually carried down by rivers, and, dividing the one by the other, obtained the quotient 97,600,000 years as the age of the ocean, supposed to be initially of fresh water. If the sea contained some salt from the beginning, this figure must be reduced accordingly. The choice of sodium is dictated by the consideration that this constituent is less removed from sea-water than any other. A relatively small correction is made for salt carried inland by the wind, and it is assumed that there is no other process of importance by which sodium is being continually removed from the oceanic waters. We may note in passing that certain observed facts, such as the evident chemical action of sea-water upon potash-granites, throw some doubt upon this assumption.

The data at Joly's command were very defective, and the main object of Clarke's memoir is to revise the calculation in the light of more recent information. In particular he has drawn upon the large mass of observations relative to the discharge, drainage-areas, and salinity of American rivers contained in the Water-Supply Papers of the United States Geological Survey. He has brought together the available information on the same points for other parts of the world, and indicated where additional observations are especially desirable. The "denudation factor," *i.e.* the number of metric tons annually removed in solution from each square mile of a drainage-basin, varies from 105 for the St. Lawrence to 16 for the Nile, and the

[1] "A Preliminary Study of Chemical Denudation." By F. W. Clarke. Pp. 19. Smithsonian Miscellaneous Collections, vol. lvi., No. 5. (Washington, 1910.)

"The Age of the Earth." By G. F. Becker. Pp. 28. *Ibid.*, vol. lvi., No. 6. (Washington, 1910.)

relative amounts of the different dissolved salts also vary widely, these variations being related to climatic and lithological differences. Clarke computes the amount of sodium annually carried down by rivers to be 175,040,000 metric tons, and the total amount of sodium in the sea $14,130 \times 10^{12}$ tons, which gives as a quotient 80,726,000 years. He apparently considers possible corrections to be unimportant, or to balance one another, for he believes this crude quotient to be "as probable as any other value that might be chosen." As representing the age of the ocean, he considers this figure, for reasons set forth in Becker's memoir, to be "certainly a maximum."

The fundamental weakness of all such calculations, whether based on sedimentation or on solvent erosion, lies in the assumption that the present annual rate represents with sufficient approximation the mean rate throughout geological time. To the present writer this consideration deprives the conclusions of even a remote relevance to the actual problem. We know, for instance, that, even during the accumulation of a single formation at a given spot, the rate of deposition may vary widely, and in a shallow-water formation may be at one time positive and at another negative. To accept the thickness of a formation as a measure of its time of accumulation, with whatever qualifications and allowances, must inevitably lead to error, and probably to a greatly exaggerated estimate of the rate of sedimentation. Like reasoning applies to all processes of chemical as well as mechanical erosion and deposition, which are necessarily controlled by varying conditions. Even if we could eliminate the effects of relatively rapid and local variations, we have still to consider probable secular changes and others of a broadly periodic kind.

A partial recognition of this side of the problem has led Dr. Becker to discard Joly's assumption of a constant rate of increment of sodium in the sea, and to adopt instead a secular change of rate. He lays stress on the fact that at present the felspathic rocks are, over great areas, covered with a blanket of rotten rock in place, which contains only a negligible amount of sodium; and he pictures a distant future, when all massive rocks may be decayed down to sea-level, and addition of sodium to the ocean will practically cease. He thus reaches the remarkable conclusion that the rate of increment of sodium in the sea is progressively *declining*, and he accordingly represents it by a descending exponential expression. The age of the ocean is calculated, according to different hypotheses, as from 74·4 millions of years. The argument is not one which is likely to convince geologists. A decayed crust covering large continental areas must certainly have existed at many past epochs, and, indeed, the present time seems to be peculiarly favoured, in that extensive tracts have been recently scoured by ice. Further, stratified deposits yield more sodium, per square mile, than crystalline rocks, and, throughout geological time as a whole, the sediments have certainly made an increasing proportion of the whole land-surface. Most geologists believe, moreover, that the total area of land-surface has, on the whole, been growing. It would be possible, therefore, to make out a strong case for a secular *acceleration* of the rate of addition of sodium to the sea. There is another consideration of even more weight. The larger vicissitudes of the earth's history indicate a certain rough periodicity, and there is good reason to believe that we are living in a time of geological activity above the average. The author himself remarks that the continents stand at present above their average level, which, of course, greatly promotes erosion; and he also recognises that the recently glaciated regions of the globe are contributing soduim to the ocean at a rate which must raise the average. Unfortunately, he is content to leave these important considerations without discussion, assuming that they are sufficiently offset by an increased marine erosion.

The second part of Dr. Becker's paper, in which he revises Kelvin's refrigeration argument, we must pass over very briefly. It is ingenious in treatment, but involves too many precarious hypotheses to carry much weight. The special feature is that no assumption is made relative to the present superficial temperature-gradient. This is eliminated by making use of Hayford's "level of isostatic compensation," which is computed to lie at a depth (71 miles) beyond any disturbance from radio-activity. Of several special cases considered, the author prefers one which gives sixty million years since the *consistentior status*, and leads to a present temperature-gradient of 1° F. in 77 feet. We may take this latter value as a crux of the whole argument. Dr. Becker remarks that it is low as compared with observation, but he fails to see that, for the gradient *due to refrigeration*, it must certainly be far too high. Here at least radio-activity cannot be left out of consideration, and, indeed, Strutt has maintained that the observed gradient can be wholly accounted for by heat generated in the outer crust of the earth. If we allow some fraction of the annual loss of heat to represent secular cooling, it still appears that the age of the earth must be enormously greater than any estimate included in Becker's supposititious cases.

A. H.

PROF. ANGELO MOSSO.

THE School of Physiology in Leipzig was the Mecca that attracted young men from all quarters of the globe to study physiology under that great master, teacher, and experimenter, Carl Ludwig. A steady stream of young, ardent, able, and talented students crossed the Alps from Italy to prosecute research and acquire a knowledge of the methods in use in the Leipzig School. Amongst the earliest of these Transalpine scholars was L. Luciani—happily still amongst us—and a little later came Angelo Mosso, one of the most illustrious of Italian physiologists, whose death at the age of sixty-four the whole physiological world to-day deplores. He was born on May 31, 1846, in Turin. After studying at his native university—with no advantages of wealth, fortune, or high social position—he, by the exercise of his own high intellectual and brilliant gifts, soon became distinguished amongst his compeers, and he was selected by Moleschott to be his assistant in the university. He also acted as assistant to Prof. M. Schiff in Florence.

Before coming to study under Ludwig in the early 'seventies of last century, Mosso had already published his well-known researches on the movements of the Œsophagus, and determined in the dog the weight that could be lifted in the process of swallowing an olive-shaped ball (1872). In fact, the study of movements of all kinds always proved to him a fascinating and fertile subject of study. At an early period of his career he made observations on the movements of the Iris, and he attributed part of the change in size of the pupil to the filling of the blood-vessels of the membrane itself. Ludwig set him the problem to study the peculiarities of the movements of the vascular wall as they can be inferred from the results of the perfusion of blood through an excised organ, such as the kidney, a method which already had yielded such brilliant results in other organs. His results were published in 1874.

Another subject of study was plethysmography. A. Fick previously had used a plethysmograph to study variations in the volume of an organ. Mosso, under Ludwig's direction, modified this apparatus, and made an elaborate study on the alterations of the volume of the human limbs under various conditions, mental and physical, or with intellectual work, for the volume of a limb does vary with mental work, as Mosso conclusively showed. Later on, years after his return to Italy, in 1884, he published his famous paper on application of the balance to the study of the circulation in man. He constructed a balance so subtle that when a person was extended on it and delicately poised, mental work caused the head end to descend from an afflux of blood towards the brain.

In 1876, after his return to Italy, Mosso became professor of pharmacology in Turin. In 1880, when Moleschott was called to fill the chair of physiology in Rome, Mosso succeeded his old teacher as professor of physiology in Turin, a post he held with the highest distinction until his death. During the last few years illness incapacitated him from working in his laboratory, a matter of the acutest mental anguish to one whose untiring brain had ever new problems to investigate and solve.

The fact that in search after health he was able to devote his enforced leisure to the study of the result of excavations made in Sicily, and, above all, in Crete, was some compensation. He has left behind him a standard work on prehistoric anthropology in his "Palaces of Crete," published in English in 1907. His first laboratory was in a convent, but his boundless activity, productiveness, and the increase in the number of scholars, as well as the growing importance of his subject, led the Government to provide him with a palatial laboratory, one of the finest, most artistic, and æsthetic and best equipped in Europe. In 1882, along with Prof. Emery, he founded the well-known "Archives italiennes de Biologie," in which many of his now classical investigations were published. The first volume contains, Bizzozero's article on the blood platelets, and that of Mosso and Pellacani on the movements of the bladder. His unrivalled activity found vent in many directions in physiology; nor was this all. He was elected a senator, and often travelled to Rome to Monte Citorio to attend to his parliamentary duties, returning at night to undertake his more academic duties in Turin next morning.

The physiology of respiration early, and indeed constantly, occupied his attention. He studied the relations between abdominal and thoracic movements in 1878, periodic respiration, Cheyne-Stokes breathing in 1886. He had a special laboratory in the Regina Margherita hut on the top of Monte Rosa, 4560 metres above sea level, for the study of life at high altitudes, and the results of his prolonged and arduous labours he published in his "Life of Man on the High Alps," which was translated into English in 1898. As human beings cannot live much more than two months at a time in these altitudes, he had a fully-equipped laboratory erected on Cold'olen at 3000 metres, where much physiological, physical, and biological work was done.

In his "Diagnostik des Pulses" (1879) he made a careful study of the pulse, and in 1895 he invented his sphygmo-manometer for the study of the blood pressure in man. Amongst the most interesting of his studies on the circulation are those on that of the brain. The temperature and psychical activities of this organ he studied in 1894, and the researches formed part of the subject of his Croonian lectures in 1892.

Perhaps his work best known in this country is that on fatigue—translated into French, German, and English—as studied by the use of his ergograph, a most valuable contribution, written with a charm of diction that one rarely finds in physiological memoirs. Mosso was a master of style, happy in his phraseology, wide and catholic in his literal tastes, a keen and loyal admirer of the poets of his beloved Italy. The bust of Dante was always present on his laboratory writing-table. His interesting work on "La Paura" ("Fear") was also translated into English. Amongst his other popular writings are "L'Education physique de la jeunesse," "Les Exercises physiques et le développement intellectuel," and "Materialismo et Misticismo."

Amongst his chemical investigations the best known are those on ptomaines (with Guaresche, in 1882), and the discovery of the fluorescent serum and the powerful toxic venin—which he called ichthyotoxin—which occurs in the blood of the Murinideæ, such as the conger eel.

In Angelo Mosso the world loses a great and distinguished physiologist, who was beloved by all who knew him, was venerated by his pupils, and by his work, both in its theoretical and its practical applications, secured for himself a reputation as an investigator and expositor such as to place him alongside that illustrious galaxy of his countrymen who have added so much to the domain of natural knowledge.

JULES TANNERY.

THE unexpected death of M. Jules Tannery on November 11, at the age of seventy-two, will be sincerely regretted by a much larger circle of admirers than he would have anticipated. He belonged to a type of mathematician which is not too common, because he was at the same time an original thinker, a successful teacher, and a writer endowed with an unusually clear, brilliant, and attractive style.

In England, at any rate, he is probably best known by his mathematical text-books. Of these, the "Leçons sur l'Arithmétique" is a masterpiece in its way, combining rigour of method with a charming lucidity and ease; the "Traité sur la théorie des fonctions elliptiques" (written in conjunction with M. Molk), is one of the best works on the subject suited for a beginner; while the value of his "Introduction à la théorie des fonctions" is shown by the fact that a second and revised edition has recently appeared. Tannery was essentially an arithmetician, and one main object of his work on function-theory is to show that (as Dirichht asserted) all its results are deducible from the notion of a whole number. A more philosophical work, dealing with the same class of ideas, is his "Rôle du nombre dans les sciences," which he appears to have regarded as his greatest work. As might be expected, he took a part in the controversies aroused by Cantor's invention of transfinite numbers.

M. Picard, in announcing the death of their colleague to the Academy of Sciences, referred in appreciative terms to the notices of mathematical works and memoirs contributed by Tannery to the *Bulletin des Sciences mathématiques*. He said:—"Elles ne sont pas toutes signées, mais on ne peut s'y tromper, car elles portent sa marque si personnelle. En les réunissant, on aurait un tableau fidèle d'une partie importante du mouvement mathématique dans ces vingt-cinq dernières années."

Tannery's last official post was that of vice-principal of the Higher Normal School, and he was elected an Academician in 1907. M. Picard bears witness to his amiable, witty, and engaging character in private life.

G. B. M.

NOTES.

SIR J. J. THOMSON, F.R.S., has been elected a corresponding member of the Berlin Academy of Sciences.

THE principal trustees of the British Museum have appointed Mr. Walter Campbell Smith, of Corpus Christi College, Cambridge, to an assistantship in the mineral department.

PROF. E. P. DI SESSA (Rome), Prof. E. G. Warburg (Charlottenburg), Prof. J. H. Poincaré (Paris), Prof. Alexander Graham Bell (Washington), and Prof. P. N. Lebedew (Moscow), have been elected honorary members of the Royal Institution.

THE sixth annual exhibition of electrical, optical, and other physical apparatus, arranged by the Physical Society, will be held at the Imperial College of Science, Imperial Institute Road, South Kensington, on Tuesday, December 20.

AT the request of the council of the Royal Society of Arts, Sir Edward Grey, Secretary of State for Foreign Affairs, authorised the transmission of the society's Albert medal to his Majesty's Ambassador at Paris for its presentation to Madame Curie. Sir Francis Bertie received Madame Curie at the British Embassy on November 25, and handed to her the Albert medal, telling her that he had been instructed by the Secretary of State to present it to her on the part of the Royal Society of Arts in recognition of the services rendered to the world by her discovery of radium, and adding that it gave him great pleasure to be the medium of carrying out the wishes of the society.

IN view of the candidature of Madame Curie for membership of the Paris Academy of Sciences, great interest attaches to the discussion at the last monthly meeting of the central administrative committee of the five French academies, on the admission of women as members of the Institut de France. According to the Paris correspondent of the *Times*, the committee was unable to agree, and it was decided, finally, that the question should be remitted to the administrative committees of the various academies, that their decisions should be considered at the next sitting on December 28, and that the whole question should be then transferred to the plenary trimestral united sitting of all the academies on January 4. It may be mentioned here that Madame Curie has just been elected an honorary foreign member of the Stockholm Academy of Sciences.

THE Vienna correspondent of the *Times* states that Mr. Alton, of the Radium Institute in London, has bought from the Austrian Ministry of Works, on behalf of Sir Ernest Cassel, 1 gram of radium for the sum of nearly 15,000*l.* The radium is a gift by Sir Ernest Cassel to the institute, and is intended for use in cancer research. One half of the gram is now being tested at the Vienna Radium Institute, and will be sent to England next month. The other half is being extracted from the pitchblende at Joachimsthal, and will be available in three or four months. Mr. J. W. Gifford, of Chard, Somerset, has announced to Prince Alexander of Teck, chairman of the Weekly Board of the Middlesex Hospital, his intention of presenting 40 milligrams of radium to the cancer research laboratories of that institution for the prosecution of their investigations. At current rates this quantity of radium, weighing approximately one seven-hundredth of an ounce, is worth about 600*l.*

THE following are among the lecture arrangements at the Royal Institution before Easter:—Prof. Silvanus P. Thompson, a Christmas course of six illustrated lectures on sound, musical and non-musical, a course of experimental acoustics, adapted to a juvenile auditory; Prof. F. W. Mott, six lectures on heredity; Dr. A. E. H. Tutton, three lectures on crystalline structure: mineral, chemical, and liquid; Dr. M. Aurel Stein, three lectures on explorations of desert sites in Central Asia; the Astronomer Royal, Mr. F. W. Dyson, three lectures on recent progress in astronomy; Dr. P. Chalmers Mitchell, three lectures on problems of animals in captivity; Prof. Arthur Keith, two lectures on giants and pygmies; Prof. W. A. Bone, two lectures on surface combustion and its industrial applications; Sir J. J. Thomson, six lectures on radiant energy and matter. The Friday evening meetings will commence on January 20, when Sir James Dewar will deliver a discourse on chemical change at low temperatures. Succeeding discourses will probably be given by Prof. W. H. Bragg, Mr. A. E. Shipley, Prof. H. E. Armstrong, Prof. Jean Perrin, Prof. Karl Pearson, Mr. J. H. Balfour-Browne, Sir David Gill, Prof. H. S. Hele-Shaw, Sir J. J. Thomson, and other gentlemen.

AN important question with regard to the distribution and occurrence of the various species of tsetse-flies in Africa is to what extent the areas infested by them remain constant. It has long been known that in a given tract of country certain parts harbour tsetse-flies, while from other parts they are absent; but of late years an impression has grown up that these areas are liable to change, and that the fly is spreading. Sir Alfred Sharpe, in a memoir on the habits of *Glossina morsitans* in Nyasaland (Bulletin of Entomological Research, vol. i., part iii.), is of opinion that fly-areas do not alter their limits to any appreciable extent. He states, however, that within the area, fly may sometimes be found in one part, sometimes in another, and in very variable quantity at different times. He believes that the numbers of the fly depend largely on the season of the year, but also on other causes impossible as yet to define. On the other hand, Mr. P. E. Hall communicates to the same journal some notes on the movements of *G. morsitans* in N.E. Rhodesia, and indicates on a map a number of areas which, to the best of his knowledge, were clear of fly up to 1906, but are now fly-infested. This conflict of opinion (perhaps more apparent than real) shows how urgent is the need of systematic investigations by expert entomologists upon these and other questions relating to the bionomics of tsetse-flies.

IN the *Philippine Journal of Science* for June Dr. R. B. Bean, of the Anatomical Laboratory, Manila, reports the discovery of a living specimen in the island of Luzon which he believes to bear close relationship to the Palæolithic type represented by the Neanderthal skull. The massive lower jaw with its square ramus and receding chin, the low cephalic index (73·68), heavy brow ridges, rounded orbits, large nasal apertures and high nasal index (102·2), combined with small stature (156·8 cm.), muscular frame and short femur, all approximate to a form similar to that of the antediluvian man of Europe, *Homo heidelbergensis*. Dr. Bean in the same issue of the Journal continues his study of the racial anatomy of the people of Taytay, dealing here with the women, whom he finds to be more primitive than the men, and closely resembling the women of Siberia. The Blend type is largely primitive in character, and the Austroloid variety comes between the Iberian and the primitive.

IN the first part of the Journal of the Royal Anthropological Institute Mr. W. Crooke discusses the origin of the Rajputs and Mahrattas, the warrior tribes of India. He identifies among the former a considerable intermixture of Central Asian blood derived from the Hun invasions, and he holds that they constitute a status group developed from a stock of which the lower grades are now represented by the Jats and Gujars of the Punjab. The Mahrattas he also considers to be a status group developed from the Kunbi tribe, and now claiming affinity with the Rajputs. He questions the validity of the suggestion that the brachycephalic element in southern India is the result of emigration of Huns or Scythians under pressure from the Aryans. It may be more reasonably accounted for by a prehistoric movement of races from the west either by the land route or in the course of commerce which existed with the Euphrates valley from a very early period.

OUR note in NATURE of November 24 (p. 114) upon the suggested inversion of the expression "thunder and lightning" leads another correspondent to point out that the phrase "animals and birds," inadvertently used on the same page, is open to the objection that it suggests that birds are not animals. He proposes the term "beasts, birds and fishes" as comprehensive and sufficiently distinctive.

DR. R. HORST has favoured us with a copy of an account of a new species of peripatus (*Paraperipatus lorentzi*) from Dutch New Guinea, published in vol. xxxii. (pp. 217–8) of Notes from the Leyden Museum. The species, which is fortunately represented by a male and a female, is of interest as filling a gap in the distribution of the group. The two specimens were discovered in moss on Mount Wichmann, at a height of between 9000 and 10,000 feet. In colour the new species is dark greenish-blue, becoming somewhat paler on the under side, and with a median central row of small whitish spots.

WHEN Dr. J. Huber succeeded Prof. E. A. Goeldi as director of the Museu Goeldi (Museu Paraense) in March, 1907, the opportunity was taken of reorganising the staff of that institution on a new and improved footing. These changes, as well as the general progress of the museum, are recorded in the reports for 1907 and 1908, which form the first portion of vol. vi. of the *Boletim do Museu Goeldi*, which, although relating to the year 1909, has only just been published. The zoological gardens attached to the museum, which are largely devoted to the exhibition of the animals of the country, appear to be in a thriving condition, having received a large number of accessions during the period under review.

THE pharyngeal teeth of fishes form the subject of an article, by Colonel C. E. Shepherd, in the November number of the *Zoologist*. These organs, except in the case of the wrasse and carp groups, have, according to the author, received but scant attention at the hands of naturalists. After referring to their different structural types, Colonel Shepherd expresses the opinion that pharyngeal teeth are probably the chief masticating organs, as they are undoubtedly in carp and wrasse. Fish-eating species, which swallow their prey whole, would have the action of the gastric juice facilitated if the bodies of the fishes swallowed had the scaly coat broken by means of the pharyngeal teeth. These teeth also assist in working the food down into the œsophagus.

THE local pearl and pearl-shell fishery forms the subject of an article by Mr. A. Seale in the July number (vol. v., No. 2) of the *Philippine Journal of Science*. Two species of pearl-oyster are found in Philippine waters, the valuable gold-lip, *Margaritifera maxima*, and the less precious black-lip, *M. margaritifera*. With the exception of those used in a factory at Manila, which is capable of turning out about 6000 gross of buttons per month, and consumes about 300 tons per annum, all the shells are exported to Singapore or Europe. Although almost the whole area from Sibutu Passage to Basilan Strait and the south shore of Mendanao is a potential pearl-bank; most of the banks have been over-fished, and it is now difficult to find productive ones. One bank was recently found in which all the shells were dead, and so corroded as to be valueless. The fisheries afford a fair yield of pearls, although much less than the Ceylon output, which comes from a smaller species, with shells of little value. On the other hand, some of the finest known pearls are the product of the Sulu fishery. The Japanese are producing pearls, although not of good shape, by introducing foreign objects into the oysters, and the author states that within the next few years it will be possible to produce perfectly spherical pearls of good lustre.

TO the Proceedings of the U.S. National Museum, No. 1778, Messrs. Everman and Latimer communicate the first complete list of the fishes of the Lake of the Woods and neighbouring waters, so far as at present known. Although the Lake of the Woods, which forms the receptacle for the waters of Rainy River, lies mainly in Ontario, its southern border is situated on the northern frontier of Minnesota, and therefore belongs to the United States. On account of the recent treaty between Great Britain and the United States, which provides for the federal control of the fisheries in these waters, an account of their fish-fauna is a matter of some importance at the present time. The fisheries in the Lake of the Woods, which are carried on by means of nets, are of very large economical value, having yielded in 1909 a total sum of 42,193 dollars, of which 28,051 pertained to the United States and 14,142 to Canada. In 1894 the total value was, however, as much as 81,337 dollars. The most valuable product is the great lakes sturgeon (*Acipenser rubicundus*), which formerly swarmed in Lake of the Woods, and in 1893 yielded no fewer than 26,000 dollars, although of late, like that of the rest of the fishery, the yield has been much less. During the last few years a slight increase in the catch is, however, reported, but this may be due to closer fishing.

IN connection with the preservation of localities where rare plants or special plant associations are found, attention is directed to a paper, by Mr. A. R. Horwood, on the extinction of cryptogamic plants, published in the Transactions of the South-Eastern Union of Scientific Societies (1910). The author discusses the numerous factors that lead to the extinction of plants, and presents the results of special inquiry with regard to Ireland, where perhaps the most destructive factor is the collector, who in the south-west counties raids the ferns *Trichomanes radicans* and *Osmunda regalis*.

IN the *Victorian Naturalist* (vol. xxvii., No. 6) is published a report by Mr. J. W. Audas on a botanical expedition in the Victorian Alps, and a list of plants recorded from the district that has been compiled by Dr. A. J. Ewart. Out of 334 species, one-third belong to the three families Compositæ, Leguminosæ, and Myrtaceæ, while the families Saxifragaceæ and Ericaceæ are only represented by *Bauera rubiginosa* and *Gaultheria hispida*; a single gentian, *Gentiana saxosa*, is found. The one endemic plant is a bushy labiate, *Westringia senifolia*.

Among the plants observed by Mr. Audas about an altitude of 5000 feet were the shrubs *Eriostemon myoporoides*, *Helichrysum rosmarinifolium*, and *Kunzea Muelleri*; near the summit of Mt. Hotham he found the grass-like umbellifer, *Aciphylla glacialis*, and a tufted carophyll, *Scleranthus biflorus*.

MR. E. P. STEBBING presents in Forest Pamphlet No. 15, published by the Government of India, a note on the preservation of bamboos from the attacks of the bamboo beetle or "shot-borer." The destructiveness of this insect, *Dinoderus minutus*, may be gauged from the fact that bamboos generally last in India only for a year or eighteen months. Cooperation between the author and the Indian Telegraph Department has resulted in the evolution of an effectual method of treatment, which consists in soaking the bamboos for five days in water, when they exude a gelatinous substance, and then immersing in Rangoon oil for forty-eight hours. The object of the bulletin is to record the experiments undertaken and the results, showing that the oil has effectually preserved bamboos treated in 1904 up to the time of writing in 1909.

THE *Agricultural Journal of British East Africa*, recently to hand (vol. iii., part i.), contains a short article by Dr. Bodeker on native methods of fishing in relation to the incidence and dissemination of sleeping sickness. Fishing is attended with grave danger to all natives in the vicinity wherever *Glossina palpalis* is found. Several districts where formerly a large population of fishermen dwelt are now uninhabited as a result of the disease. Among remedial measures, the destruction of the thin strip of bamboo canes along the whole coast-line is recommended. In another article Mr. MacDonald urges the advantages of maize as a crop for export. It can be grown readily and at comparatively low cost over a large area of the country, and, so far, it has not been infested by any seriously destructive pest. Railway rates to the coast being now much reduced, it becomes possible to send the maize to Great Britain or to the Continent, where the demand is practically unlimited.

A TABLE is given in a recent issue of the *Journal of Agriculture of South Australia* (vol. xiv., No. 1) showing how the use of fertilisers for cereals has increased during the past thirteen years. From 1898, the first year given in the table, to the current year the increase has been continuous; some of the figures are as follows:—

Year	Quantity of manure used Tons	Area of cereal crop manured Acres
1898	12,500	250,000
1899	16,500	350,000
1907	61,000	1 366,400
1908	65,000	1,456,000
1909	76,500	2,100 000
1910	87,000	2,320,000

A few soil analyses are recorded in another article, from which it appears that the soils are very different from our own. The nitrogen varied from 0·026 to 0·091 per cent., the phosphoric acid from 0·010 to 0·045 per cent., and the potash from 0·044 to 0·82 per cent. All these values are much lower than in ordinary English arable soils.

THE Natal Museum has issued a catalogue of a collection of rocks and minerals from Natal and Zululand arranged stratigraphically by Dr. F. H. Hatch. The specimens were collected by Dr. Hatch during the winter months of 1909. Beginning with the oldest rocks, the order of arrangement is:—(1) metamorphic rocks, Swaziland system; (2) granites intrusive in the metamorphic rocks of the Swaziland system; (3) Waterberg or Table Mountain sandstone; (4) rocks of the Karroo system; (5) surface deposits. The collection of specimens is a duplicate of one which Dr. Hatch proposes to present to a London museum.

IN a paragraph upon the recently discovered ice-cave near Obertraun, Upper Austria, which appeared in NATURE of October 13 (p. 469), Prof. E. Fugger was described as one of the explorers of the cave. Prof. Fugger asks us to state that he has not yet personally examined the cave, and that the information he kindly sent at our request was provided by Herr Alexander von Mörk, who took part in the exploration of it. The discoverers and first explorers of the cave were, according to reports in the Linz newspapers, Herren J. Lahner and Kling (Linz), J. Pollak (Wels), I. Bock (Graz), A. v. Mörk (Salzburg), and L. Kranl (Budapest).

MESSRS. OUTES AND BÜCKING have added notably to the discussion of the *tierras cocidas* of the Pampas beds of Argentina by publishing photographs of thin sections of the debatable materials ("Sur la structure des scories et 'terres cuites,'" *Revista del Museo de la Plata*, vol. xvii., p. 78, September). Scoriæ are figured from Monte Hermoso which are undoubtedly of volcanic origin. These are contrasted with the fragmental earths, which contain, however, volcanic particles. When these earths are subjected to the action of fire, they show fluidal structures and a glassy ground between the surviving fragments, and certainly do not resemble the alleged "terres cuites" selected for comparison. True burnt earths are formed during agricultural operations near La Plata when the settlers wish to clear their ground by burning the surface-vegetation, and these are of the glassy type. It is urged, therefore, that the andesitic scoriæ which occur in the earths of the Pampas beds cannot be regarded as products of superficial burning. The petrographic argument is immensely strengthened by the illustrations, and their production, if we may judge from a quotation made by the authors, seems due to certain remarks published in NATURE in 1909 (vol. lxxxi., p. 535).

IN the September Bulletin of the American Geographical Society, under the title of "Notes on the Description of Land Forms.—I.," Prof. W. M. Davis returns to his attack on the "empirical" method of description in a criticism of three recent geographical papers (German, Italian, and English). He urges that it is "ultra-conservative" to adhere to the empirical method when "the whole trend of modern physical geography is toward the use of explanatory description." It may be replied, however, that while the new "terms of origin" can be sometimes used with good effect by a physiographer of Prof. Davis's experience and confidence, they might be more misleading than any empirical description if employed wrongly or applied without sufficient warrant. It is not every traveller who could be trusted with the use of "mature insequent ravines," &c., as desired by Prof. Davis in his "Notes."

THE November issue of the *National Geographic Magazine* contains thirty-nine photographs in colour, which is the largest number of coloured pictures ever published in a single number of the magazine. These illustrations all deal with life and scenes in Korea and China, and together provide an excellent means of picturing the habits and customs of these Eastern peoples. The article which is illustrated by these pictures is by Mr. William W. Chaplin, who shows an intimate acquaintance with the countries he describes, and he also took the photographs

from which the pictures were made. Mr. Guy E. Mitchell contributes a well-illustrated paper on a "New Source of Power," in which he deals with the extensive beds of lignite in the United States. The State geologists have estimated that the lignite deposits in the United States, exclusive of Alaska, amount to 740×10^9 tons, of which fully one-third belongs to the public lands. The total area underlain by lignite and sub-bituminous coal—coal mostly of little, if any, value in steam plants, but of great efficiency in gas producers—is 246,245 square miles. The U.S. Geological Survey fuel tests have showed that when coal is made into producer gas and then used in a gas engine, it has from two to three times the efficiency that it has when burned under a steam boiler in the ordinary way. Moreover, the experiments showed that lignite, which is useless for steaming purposes, can be used most successfully in the gas producer. Other articles in this issue of the magazine are "Kboo, a Liberian Game," by Mr. G. N. Collins; the "Pest of English Sparrows," by Mr. N. Dearborn; and "The Mistletoe," by Mr. W. L. Bray.

The remarkable series of earthquakes that occurred in Alaska in September, 1899, is described in a valuable paper by Mr. Lawrence Martin (Bulletin of the Geol. Soc. of America, vol. xxi., 1910, pp. 339–406). The first known shock occurred on September 3, the last on September 29. In these four weeks there were four, possibly five, world-shaking earthquakes, and several hundred minor shocks. The strongest of all was the second great shock of September 10. It disturbed an area of probably not fewer than 432,000 square miles, and produced water-waves in Lake Chelan, Washington, which is nearly 1200 miles from the origin. Shore-lines were raised as much as $47\frac{1}{3}$ feet, and depressed 5 feet or more in Yakutat Bay, and new reefs were uplifted. Sea-waves 20 or 30 feet high swept the shores. The Muir Glacier subsequently retreated eight miles in as many years, while other glaciers were subject to brief spasmodic advances. But, though the earthquake ranks among the greatest that have visited the American continent, there was no recorded loss of life among the twenty thousand inhabitants of the disturbed area, while the destruction of property was insignificant. This immunity was, no doubt, due to the fact that the people lived in tents, log cabins, or low frame buildings.

In *Bergens Museums Skrifter. Ny Raekke.*, Bd. i., No. 1, Dr. A. Appellöf, of the Bergen Museum, describes the investigations on the life-history of the common lobster, upon which he has for a number of years been engaged. The monograph ("Untersuchungen über den Hummer") contains also a summary of previous work on the subject, and, as a whole, gives the best account of our knowledge of the natural history of the lobster which is at present available. With regard to the migrations of the animal, Dr. Appellöf, basing his opinion chiefly on the results of marking experiments, concludes that the lobster is a stationary animal, and remains in a very restricted area for many years, undertaking only short migrations, a conclusion which is of great importance when possible schemes for stocking a fishery by means of artificial rearing of lobster larvæ are under consideration. The author considers that the probability of increasing the supply of lobsters on the fishing grounds by means of artificial hatching, combined with the rearing of the larvæ until they reach the bottom-haunting stages, is very great, and refers to the successful rearing experiments carried out by Mead in the United States. The monograph is illustrated by a series of plates showing the various stages of development of lobster larvæ.

We have received from Mr. A. Ghose a letter with reference to the review in Nature of September 29 (p. 406) of his paper on "Manganese-ore Deposits of the Sandur State." Mr. Ghose points out that the Indian outputs of manganese ore were quoted incorrectly; our reviewer regrets the error, and supplies the correct figures as follows:—Production of manganese ore in the State of Sandur during 1908, 23,413 tons; during the quinquennial period 1904–8 (four years), 50,872 tons. Production of manganese ore in the Presidency of Madras during 1908, 118,089 tons; in the quinquennial period 1904–8, 513,845 tons. Production of manganese ore in the whole of India during 1908, 685,135 tons; in the quinquennial period 1904–8, 2,545,718 tons. The production of Sandur is therefore a little more than 3 per cent. of the whole output of India.

The meteorological chart of the North Atlantic for December (first issue), published by the Meteorological Committee, has some interesting details of the two West India hurricanes experienced during October last. A cablegram from Havana on October 13 stated that the barometer was then falling, and later on a destructive cyclone passed over the south of Cuba, and was central between there and Cay West on October 15. On October 17 another storm of greater intensity (referred to in London newspapers on October 19) passed over Havana, and the island of Cuba is reported to have sustained the greatest material damage in its history. Several steamships were driven ashore by one or other of these hurricanes. Interesting synoptic weather charts are also given for the period November 10–16. These and the useful explanatory text indicate the existence of three high-pressure areas, one over the western American States, another to the north of Iceland, and a third which was gradually transferred from Europe to the region of the Azores. Over Europe as a whole the weather was dominated by depressions developed over the upper portion of the Atlantic, between the Icelandic and Azores high-pressure systems.

We have received from the Abbé T. Moreux, director of the Bourges Observatory (Cher), a revised edition of his pamphlet entitled "Introduction to the Meteorology of the Future: the Sun and the Prediction of Weather." The Abbé is dissatisfied with the present method of forecasting weather for a day or two in advance. He points to the changes in the sun, which seem to have some connection with those on the earth, and asks whether this is not something more than a simple coincidence. He quotes step by step the progress made in tracing this connection from the time that Sir W. Herschel discussed the question of sun-spots (Phil. Trans., 1801, p. 265), and rapidly passes in review the labours of Schwabe, Wolf, and subsequent investigators down to the present day, and many references are given to the discussions which have appeared in our columns and elsewhere. The spectroscopic researches and discoveries of Sir Norman Lockyer and M. Janssen, and the establishment of the Solar Physics Observatory at South Kensington, are referred to as of prime importance; the former marked the epoch of extended observations on the simultaneity of solar and terrestrial changes, and the latter formed a base for similar inquiries in other parts of the world. The author observes that we have now an important groundwork of operations, and it must be maintained at any price.

In two notes published in the *Bulletin International* of the Academy of Sciences of Cracow (March and April) Dr. Const. Zakrzewski communicates the results of measurements made by him on the dispersion of metallic

bodies in the visible spectrum. Two experimental methods were used:—(1) The author's "elliptic analyser," described by Dr. Zakrzewski in 1907, and used since with success by Herr Volke; as shown in the paper, this arrangement provides a comparatively exact way for the determination of the refractive index ν and of the index of extinction κ for a metallic body. (2) A new scheme depending on the use, for the observation of ellipticity, of a convergent pencil of light; the results thus obtained are estimated to be correct within 5 per cent. of their values. Illustrative results for platinum, cobalt, and graphite are adduced. Maxwell's simple equation $\nu^2 - \kappa^2 = \text{const.}$, now given up on theoretical grounds, is found to hold true for graphite. The second correlative equation, however, asserting the proportionality of the product $\nu\kappa$ with the period of vibration in the incident beam of light, does not agree with the observations.

An interesting address on "Comets and Electrons" was delivered by Prof. Augusto Righi to the Bologna Academy on June 22, and is published as No. 13 of *Attualità scientifiche* (Bologna: Nicola Zanichelli, 1910, price 2.50 lire). In the paper Prof. Righi traces the growth and development of ideas regarding radiation-pressure, the successive proofs, disproofs, and reproofs of its existence for finite bodies, for minute solid particles such as are believed to exist in comets' tails, and for gaseous molecules, the theory of formation of the tails themselves, the electrical phenomena accompanying them, the escape of gases from planetary atmospheres, the nature of sun-spots and allied astrophysical phenomena. Prof. Righi, in conclusion, refers to the experiments conducted during the passage of the earth through Halley's comet, a large proportion of which gave rise to no definite conclusions. The following suggestive remark occurs in the paper:—"In this connection of the action of radiations on the individual molecules of a gas, and hence on the presence of gases in comets' tails, there has been once more verified the not uncommon fact that conclusions which are just, or regarded as such, are reached only by an asymptotic method, that is, after a series of successive corrections, and often, as in the present case, after having completed a series of successive oscillations, fortunately of decreasing amplitude, from one side to the other of the truth."

A committee was appointed about two years ago by the Institution of Civil Engineers to investigate and report on questions connected with the use of reinforced concrete. A preliminary and interim report has now been issued giving information regarding the conditions under which reinforced concrete has been employed in engineering work in various countries, and the views of engineers having special experience in its use. The committee does not accept any responsibility for any of the statements contained in the report, and reserves its own views and recommendations until later. Hence the designer will still have to depend largely on the excellent report presented some time ago by the Royal Institution of British Architects, more especially as he will find difficulty in extracting definite information from the present report. The reader is expected to compare for himself the various statements of opinions contained in 262 pages of letterpress. The committee is now engaged upon tests and investigations in order to enlarge the knowledge at present available, and no doubt more definite information and conclusions will appear in a subsequent report.

Messrs. Newton and Co. have been granted a warrant of appointment as opticians to the King. They have held Royal warrants for more than sixty years.

OUR ASTRONOMICAL COLUMN.

Ephemeris for Faye's Comet, 1910*e*.—Dr. Ebell publishes a continuation of the ephemeris for Faye's comet in No. 4457 of the *Astronomische Nachrichten*; the following is an extract:—

Ephemeris 12h. (Berlin M.T.).

1910	α (true) h. m.	δ (true) ° ′	log *r*	log Δ	mag.
Dec. 6	3 37·1	+3 44·0	0·2270	9·8717	10·3
,, 10	3 37·6	+3 25·0	0·2292	9·8845	10·3
,, 14	3 38·5	+3 12·8	0·2316	9·8985	10·4
,, 18	3 39·8	+3 7·1	0·2342	9·9134	10·5
,, 22	3 41·6	+3 7·5	0·2371	9·9290	10·6
,, 26	3 43·7	+3 13·3	0·2401	9·9453	10·7
,, 30	3 46·3	+3 24·1	0·2433	9·9621	10·8

This ephemeris is calculated from Prof. Stromgren's elements with a correction ΔM., and the time of perihelion is brought forward by about +8·91 days, to November 1·647 (Berlin M.T.); an observation at Teramo on November 23·4 gave a correction of −9s., −2·1′, to the ephemeris position.

Recent Helwan Photographs of Halley's Comet.—Halley's comet was again photographed with the Reynold's reflector at the Helwan Observatory on November 7, 9, and 11, and the plates indicate a correction of +0·2m., 0′, to the ephemeris published in No. 4450 of the *Astronomische Nachrichten*; the magnitude is estimated at about 14·5.

A telegram from Prof. Frost announces that Prof. Barnard observed the comet (presumably with the 40-inch refractor) at the Yerkes Observatory on November 11 at 17h. 17·8m. (M.T. Yerkes), and found its magnitude to be about 11·0; the observed position was

R.A. = 12h. 4m. 21·3s., dec. = −14° 54′ 15″.

From these observations it would appear that there is a marked difference between the photographic and visual magnitudes, and, curiously enough, it seems that the visual brightness is the greater (*Astronomische Nachrichten*, No. 4457).

The Total Eclipse of the Moon on November 16.—Some interesting notes dealing with observations made during the recent eclipse of the moon appear in No. 21 of the *Comptes rendus* (November 21). MM. Luizet, Guillaume and Merlin, at the Lyons Observatory, observed the occultations of several stars, and found that in some cases the disappearances were not instantaneous. In two cases the star appeared to be projected on the disc before disappearing, and in one case contact with the limb preceded disappearance by three seconds. On the other hand several well-observed occultations and reappearances were quite sudden.

M. Montangerand, Toulouse Observatory, noted that in one case the extinction took an appreciable time, but in two others it was instantaneous; he also directs attention to the apparent unevenness of the shaded disc. M. Lebeuf, at Besançon, also noted this phenomenon, and describes the apparent rotation of the deeper coloration as the eclipse proceeded. The general transparency of the shadow, as compared with earlier eclipses, notably that of April 11, 1903, also attracted his attention.

M. Jonckheere, at the Hem Observatory, was able to see the penumbral shadow, with the naked eye, at 10h. 32m., and observed first contact with the shadow at 10h. 57m. 5s. (M.T. Hem). He also records that the meteorological observations, presumably delicate, indicated a sensible lowering of temperature during totality.

The Probable Errors of Radial-velocity Determinations.—The radial velocities of stars are now being measured by many observers, not always with concordant results, and it becomes important that the probable errors of such observations should be investigated and defined with every care. In a paper in No. 3, vol. xxxii., of the *Astrophysical Journal* (p. 230), Mr. Plaskett deals with this subject, basing his discussion on exhaustive experiments he has made at the Ottawa Observatory. Many factors enter the problem, and one of the most important is the effect of dispersion. Mr. Plaskett finds that, contrary to expectation, the accuracy is not inversely proportional to the dispersion of the spectrograph used, only a

small increase of probable error, say 40 per cent., appearing when the dispersion is divided by three.

In the early-type stars the diffuseness of the available lines in the spectrum increases the probable error very rapidly, and Mr. Plaskett is convinced that physical causes in the star's atmosphere are contributory to this increase.

For solar-type stars it would appear that the average probable error of a good three-prism determination need not exceed ± 0.5 km. per sec., while with one prism ± 0.70 km. might be expected in good work. If stars of an earlier-type spectrum are dealt with, ± 2 to ± 11 km. per sec. is a moderate estimate of the probable error. Finally, Mr. Plaskett suggests that with solar stars the greater part of the error accrues from instrumental causes, the errors of measurement only accounting for about one-third or less.

THE PHOTOGRAPHIC MAGNITUDES OF STARS.—In Circular No. 160 of the Harvard College Observatory Prof. E. C. Pickering discusses the progress made, to July, in the establishment of a method for determining photographic magnitudes and of a scale for recording them.

Three methods have been found to give satisfactory results. The first depends upon the law that stars of the same spectral class have the same colour and has been tested with concordant results; the following values are interesting as giving the constants necessary to reduce photometric to photographic magnitudes according to spectral class:—

B	A	F	G	K	M
−0·31	0·00	+0·32	+0·71	+1·17	+1·68

Thus if the visual magnitude of a star is 5·00 and the spectrum is of type B, the photographic magnitude is 4·69, but if the spectrum is of the G type the photographic magnitude is 5·71.

The second method, in which a standard "polar sequence" of stars is photographed on the same plate and under similar conditions as the stars to be measured, has been already described in these columns, but it is interesting to note that the work has been extended to stars so faint as the twentieth magnitude, and it is hoped, ere long, to publish definitive magnitudes for a great number of stars in both hemispheres. About 11,000 measures of 200 photographs have already been made; for stars fainter than magnitude 14, for which long exposures are necessary, it has been found that this method is not so suitable. For such stars it has been found that the third method, in which a small circular prism of very small angle is attached to the centre of the objective, is better; the small prism diverts a known proportion of the light from each image into a secondary image, and so provides a ratio scale. Prof. Pickering discusses the difficulties presented by the problem, and states that although the results already attained are very hopeful, much remains yet to be done.

The same problem is also attacked by Herr E. Hertzsprung in No. 4452 of the *Astronomische Nachrichten*, who proposes a tried method in which the density of a direct image is compared with an image, on the same plate, produced when a grating is placed before the objective.

PROPER MOTION OF THE STAR B.D.+33° 99.—Whilst making observations of the minor planet 1910 KU, Dr. Abetti was led to suspect that one of his comparison stars, B.D.+33° 99 (AG. Lei. 226), has a large proper motion. Subsequent investigation and calculations show that this proper motion amounts to $-0{\cdot}027 \pm 0{\cdot}004$s. and $-0{\cdot}34 \pm 0{\cdot}00''$. The magnitude of this star is 8·5 (*Astronomische Nachrichten*, No. 4453).

THE NEW METEOROLOGICAL OFFICE.

ON Thursday, December 1, a large party assembled at the new Meteorological Office at the corner of Exhibition Road and Imperial Institute Road on the invitation of the Meteorological Committee.

The committee was originally appointed by H.M. Treasury in 1905 to control the administration of the Parliamentary grant for meteorology. Its inexpressive title gives little indication of its responsibility to the country and, indirectly, to the world at large. It consists of the director of the office, Dr. W. N. Shaw, who is *ex officio* chairman; the hydrographer of the Navy, Rear-Admiral H. E. Purey Cust; Mr. G. L. Barstow, of the Treasury; Captain J. M. Harvey, of the Board of Trade; Mr. T. H. Middleton, of the Board of Agriculture and Fisheries; with Sir G. H. Darwin, F.R.S., and Prof. Arthur Schuster, F.R.S., the nominees of the Royal Society.

The work of the office goes back, in continuity, to the original establishment of a Meteorological Department of the Board of Trade for the joint service of the Navy and the mercantile marine under the superintendence of Admiral FitzRoy, the naval officer who, as captain of the *Beagle*, had carried Charles Darwin round the world. The motive power for the establishment of a special department for meteorology came from a maritime conference held in Brussels in 1853, in which Lieut. Maury, of the United States Navy, a well-known geographer and meteorologist, took a leading part. The primary object of the office was the collection and discussion on an organised plan of meteorological observations made at sea; but when Leverrier began collecting daily observations by telegraph in France, FitzRoy associated himself with the idea, and in 1860 he introduced a system of weather telegraphy with storm warnings and forecasts which in 1861 were published in the newspapers.

This line of action evoked a great deal of criticism on the part of scientific authorities, and it is doubtful whether meteorology, at that time a bashful *débutante* among the sciences, has ever been forgiven for so shocking a *faux pas*. It is true that the system of warnings was continued after FitzRoy's death at the instance of the Board of Trade, influenced by several memorials to Parliament, and that in 1879, after the issue of forecasts had been dutifully suppressed for twelve years, in a report of the council then in control of the office, appointed by the Royal Society and made up of the great names of Henry J. S. Smith, Warren De la Rue, Frederic J. O. Evans, Francis Galton, George Gabriel Stokes, and Richard Strachey, the following paragraph appears:—"For several years forecasts not intended for publication had been daily prepared in the office, and the experience thus gained by the staff has emboldened the council to announce their readiness to commence in April, 1879, the issue to the public of forecasts for the different parts of the United Kingdom," and that the issue has been continued ever since; but the natural hesitation which men of science feel about publishing their conclusions before they have had an opportunity of verifying them has always overshadowed that side of the office work. To that circumstance, combined with the frigidity with which the young science has been treated by her elder sisters, it is probably due that, while prolonged effort has been devoted to the preparation of forecasts twice, or even three times a day, for a whole generation, and while the rule that no forecast shall be formulated without first setting out the data and the grounds for the inference has been rigorously enforced, yet the issue of the forecasts has been left practically to the newspapers. It seems otherwise inexplicable that no general system of distribution of forecasts by telegraph should have been adopted in this country.

FitzRoy died in 1865, and the office became the subject of inquiry by a Government committee, with the result that in 1867 the control of the Parliamentary grant was handed over to a committee of the Royal Society, with Sir E. Sabine, the president of the Royal Society, as chairman. At the same time provision was made for marine meteorology and weather telegraphy to be associated with the work of fully equipped meteorological observatories of the first order, six of which were forthwith established, namely, Falmouth, Stonyhurst, Aberdeen, Glasgow, Armagh, and Valencia, in addition to Kew, which had become the central observatory of the system.

Continuity between FitzRoy's department and the Meteorological Office was maintained by the transfer of all the duties of the department and a number of members of the staff to the new committee. Mr. T. H. Babington, however, who took over the management of the department on FitzRoy's death, was not transferred; Mr. R. H. Scott was appointed director of the new establishment with

Captain H. Toynbee as marine superintendent. The office occupied the quarters at 1 and 2 Parliament Street, belonging to the Board of Trade, which accommodated FitzRoy's department; but to its chagrin it was dispossessed in 1869, and the ejected committee hired accommodation for itself in the form of a residential flat over a shop at 116 Victoria Street.

In 1875 another Government committee of inquiry was constituted, with the result that in 1877 the direction of the office became vested in a council appointed by the Royal Society. This constitution lasted until 1905, when, as the result of a third committee of inquiry, the present system was adopted, under which the office is managed by a director with an advisory committee appointed by the Treasury. Throughout the period of the council the office occupied the premises at 116 Victoria Street, which during its tenure was renumbered 63.

It cannot be said that the council regarded the suite of offices which they occupied as ideal accommodation for the Office; but it was generally hampered for want of funds, and, as a matter of practical politics, the idea of new accommodation may be attributed to Sir H. Maxwell's committee of 1903, which pronounced the accommodation at Victoria Street to be unsuitable. The advantage of housing the office under the same roof as a post office had long been recognised, and the wish of the Post Office to have a permanent structure at South Kensington on land which formed part of the estate of the Commission for the Exhibition of 1851 led, at the suggestion of a member of the Meteorological Committee, to an arrangement by the Treasury for the committee to rent from H.M. Office of Works more spacious accommodation than they had at Victoria Street at practically the same rent. The arrangement was concluded in May, 1907, and the transfer of the work to the new premises was completed on November 15, 1910. The party on December 1 was intended to give those interested in the work of the office an opportunity of seeing the new premises newly equipped.

This long introduction is necessary, because the office has now fifty-six years of history behind it, passed in a habitation chosen with a view to the collection and discussion of observations from sea and land. During that time it has been responsible for supplying meteorological instruments to the Navy, the mercantile marine, its own stations, and recently to colonial Governments, and it has become the controlling centre of more than 500 stations of various kinds in these islands and in various colonies, while it has instruments on more than 200 ships afloat, and is in direct communication with nearly all liners crossing the Atlantic. It has made a vast collection of observations from ships in the form of log books which fill 500 feet of shelving. It deals with about 50,000 telegrams a year in its telegraphic branch. The independent existence of the British Rainfall Organisation, founded as a private enterprise by Mr. G. J. Symons, a member of FitzRoy's staff, exonerates it from dealing fully with the statistics of rainfall, but for more than forty years it has aided the meteorological societies of London and Edinburgh in the collection of climatological data for the British Isles, and has gradually become itself a centre for the compilation of returns from volunteer observers all over the country and from some of the colonies. To this collection is added the published meteorological data of all the countries of the world, forming a library almost unique of its kind. It has issued publications to the number of about 250 volumes, which, being in the form of Bluebooks or of unwieldy atlases or charts, are little read. So far as the general public is concerned, it appeals to them only through the forecasts which the newspapers are kind enough to issue for it, through the storm signals which are occasionally visible on the coasts, and through certain fishery barometers supplied to coast stations, which are, however, mostly marked with the initials B.T., because the official in charge was unwilling to recognise as *de jure* the dissociation *de facto* of the office from the Board of Trade.

Until quite recently, partly on account of the apathetic attitude of the universities, partly because meteorology deals with British units and other sciences use metric units, the education of the people in the new science had not ever been begun. The meteorology of Daniell and Herschel had been, in fact, allowed to fall out of the educational curriculum, and its place was taken by sciences with which the teachers were themselves acquainted.

In moving their home from Victoria Street to South Kensington the Meteorological Committee has set itself to change all this. They have sought to secure, with what success the public may now judge, space in which their collection of books and records can be reasonably well housed, and which at the same time affords an opportunity to display, for the information of the public, a series of exhibits which show what the work of the Meteorological Office has been in the last fifty years, what its work is now, how it does it, and what its purpose is in doing it. Those who have visited the office will agree that the idea of combining a library with a museum has elicited very generous sympathy from the Office of Works, and that the architect of the new building, Sir H. Tanner, has dealt with the problem, which is not without difficulty, in a manner for which admiration is not too strong a term to use. The space is perhaps a little over full, as the library has even now to accommodate part of the working staff of the office in addition to its other requirements; but when it is remembered that rent is still a consideration to be reckoned with by the committee, there is, after all, little to complain of.

The office premises are mainly on the first and second floors of the new building at the corner of Exhibition Road and Imperial Institute Road. These two floors provide, besides the library and its ante-room, a room for the director and rooms for the four superintendents and for the director's secretary, a large room for the clerical staff and another for the forecast staff, three rooms for the marine staff, and two for the instruments staff. To judge by external appearances, the whole building might be regarded as a post office, but it is not so. The ground floor and the greater part of the basement is assigned to the post office, but in the basement the Meteorological Office has space which it is hoped may provide for a printing office as well as a workshop. A small physical laboratory is provided on the third floor, the remainder of which is temporarily occupied by the staff of the Science Museum. Access is given thereby to a large flat roof, which provides invaluable opportunity for the exposure of instruments for the purposes of trial and investigation.

The manner in which the committee have utilised the space at their disposal and have kept in view the educational purposes which have been indicated will be evident from the list of exhibits prepared for the party on December 1.

In a case outside the doorway is exhibited the most recent information about the current weather, based on the telegrams received. In the outer lobby, opposite the door of the post office, is a case containing a barograph, the recording apparatus of a Callendar thermograph, and of a Dines pressure-tube anemograph, exhibiting the continuous record of pressure, temperature, and wind velocity. On the walls of the inner lobby and the staircase leading to the first floor are a series of frames showing the course of the seasons in the British Isles as determined by the weekly averages since 1878. The relation thereto of the weekly values of the current season for four divisions of the country is shown upon transparent paper, which covers the diagrams of average variation. These diagrams lead up to one which shows how the meteorological elements at the several stations in the same district may vary under similar types of weather. Four frames show the monthly meteorological charts of the Atlantic and Indian Oceans, and further on is a diagram showing the variation of temperature in the upper air on various occasions in 1908 up to 15 miles or more, in juxtaposition with a series of photographs of clouds presented to the office by Dr. W. J. S. Lockyer.

The catalogue of exhibits makes reference to a series of three cases on the first-floor hall intended to illustrate the work of the office under FitzRoy at the Board of Trade, under Sabine and Scott, of the Meteorological Committee of the Royal Society, and under the Meteorological Council, with Smith and Strachey, successively, as chairman, but for reasons not given in the programme the cases are not yet there; some of the exhibits are to be found compressed into a single case in the upper corridor.

The hall accommodates, however, a radiation recorder by Callendar and a hyetograph or rain recorder of Negretti and Zambra's most recent pattern.

From the hall we pass to an ante-room provided with a counter for the supply of information of various kinds, and leading to the library and museum on the one side and to the headquarters of the clerical and inquiry staff on the other. This room, with the library and the staircase, are finished throughout with ornamental woodwork in Austrian oak. Round the ante-room are glass cases for the display of barograms from ships and land stations, anemograms and other records of importance to aëronauts, and also cases devoted for the present to diagrams prepared in the office to show results deduced from data for the whole globe or for British observatories or stations, including the relationships of meteorology and agriculture. A diagram, newly prepared, showing the distribution of rainfall throughout the day for the several months of the year at Kew and Valencia, is specially noticeable. In the same room is the Kelvin harmonic analyser constructed for the council to be used for the analysis of barograms and thermograms. A relief map of the British Isles on the scale of one-millionth, intended for the central space, being unfinished, was represented by a cast of the English section.

On either side of the entrance to the library and museum are square kiosks for envelopes, the faces of which are framed in glass and used for displaying the weekly sets of records from observatories, the records of sunshine at ninety-two stations for a single day of last summer, and the winter sunshine records of 1909–10 in London, Cambridge, and Eastbourne. Within the library, in four cases, are displayed a series of exhibits in connection with marine meteorology, the daily service of forecasts and storm-warnings, climatological statistics, and the investigation of the upper air. Another and larger case is devoted to the observatories at Kew and Eskdalemuir. Four small cases show a new method of representing data for the whole world on what is called a developable globe. The current daily weather charts of all countries and the latest climatological reports from the British Dominions are collected together in special cabinets. Two glass cases face one as one enters the museum: one contains specimens of the normal instruments adopted by the office, the other such examples as the office possesses of the corresponding instruments of other countries.

The library is divided into six compartments by bookcases extending from the side walls. In four of the compartments the books of published data are grouped according to countries, the remainder being occupied by periodicals, text-books, &c. The recesses of three of the bays are used by the working staff of the statistical and library division of the office; two are furnished with tables for students, and on the book-cabinets near by the latest additions to the library are displayed. A few educational exhibits, lantern-slides, photographs, &c., including some valuable stereophotographs of clouds from a long base, by Mr. J. Tennant, were set on Thursday on one of the tables.

The library is not large enough to contain all the books and documents belonging to the office. Accordingly, the manuscript records of observations at stations of various kinds find a place in the room of the superintendent of statistics. The original working charts of the Daily Weather Service are housed with the files of daily synchronous charts of all kinds in the forecast room, a spacious room on the second floor in direct connection by means of pneumatic tube with the instrument room of the post office. The series of meteorological logs from ships, now exceeding 13,000 in number, is housed in the working rooms of the marine staff; the books of data extracted from them are in the marine superintendent's room or in the passage near by. The stock of instruments is housed in the rooms of the instruments staff, while separate store rooms are set apart for publications and for observatory records. These latter are already too numerous for the accommodation provided. The bound volumes of anemograms are therefore stored on shelves elsewhere, and for the time being the sunshine cards are in the basement, where it is proposed to construct with them a 13-inch wall 50 feet in length and 10 feet high.

One of the main difficulties connected with the removal has been the housing of the enormous collection of records and documents, the accumulation of upwards of fifty-six years. The problem of the ultimate fate of these accumulations is one which has now to be faced.

The new arrangement of the office, which is open to the public, has chiefly in view the educational advantages which a library and museum can afford; but it has another object. One often hears a distinction drawn between routine and research, sometimes to the disparagement of the work of an office. Routine work in meteorology is really and truly cooperative research; if not it ought to be discontinued, for it has ceased to have any object. Research in the more restricted sense means personal research upon a subject selected by the individual taste. In co-operative research one cannot choose one's subject; it has been chosen for us by international agreement, by conferences and congresses, by committees perhaps, or by other circumstances over which we have no immediate control. What is still left to our free choice is whether the co-operative research shall be manifestly our research or other people's research. Routine becomes sterile when it is a listless contribution to other people's research. To keep cooperative research alive we need to keep very close up to the working face of the bore into the unknown. It may take a generation or more to carry the whole work through, and premature publication may be worse than routine. To put the record of our progress in a shape in which it can be seen by those who appreciate it, as well as those who do not, gives us a place in the ranks of conscious workers for a definite, even if a distant, object.

W. N. Shaw.

THE CLAIMS OF SCIENTIFIC RESEARCH.

THE anniversary dinner of the Royal Society was held as we went to press last week. Lord Robson proposed the toast of "The Royal Society," and it was replied to by Sir Archibald Geikie, K.C.B., president of the society. In the course of his remarks, Lord Robson pointed out that in nearly every direction the labour and research of science, however remote they may sometimes seem from the affairs of the workshop or the office, are opening up new and almost illimitable sources of wealth and new avenues of profitable employment. It is the man of science who is to decide the fate of the tropics; not the soldier, or the statesman with his programmes and perorations, but the quiet entomologist. He is the man of science who of all others strikes popular imagination the least, and gets less of popular prestige; but he has begun a fascinating campaign for the sanitary conquest of those enormous tracts of the earth, and before long he will have added their intensely fertile soil, almost as a free gift, to the productive resources of the human race. The report in the *Times* states that Lord Robson continued as follows:—

"Not long ago it was my duty to consider legislation in reference to the most complicated problems of overcrowding in cities. That is essentially a problem for statesmen, but not for statesmen alone. Perhaps the most hopeful attack on overcrowding is being unconsciously made by those men of science who have lately done so much to improve the transmission of electric power. They are on the way to make it possible and profitable for factories to establish themselves away from cities and coal-pits, and yet have the exact amount of power they want each day for their machinery sent down to them every morning by wire at a trivial cost. Some day manufacturers will begin to go back to the land, and we shall regard engine-building or soap-boiling as rural occupations. We look to you, the men of science, and almost to you alone, to ensure, not only that our centres of population shall not be congested, but also that our cities, now smoke-laden and devitalised, shall not be polluted. I have spoken of a sanitary conquest of the tropics. Give us also a sanitary conquest of the air of England. What a programme of social reform the Royal Society has got! Yet I have not heard that you are making any claims on the Development Fund. In all seriousness and earnestness, I contend that you ought to be the most favoured, as you would certainly be the most meritorious, of all claimants on that reservoir of national generosity. The various sections and interests who are on the way to absorb it all

are seeking, I believe, without exception, to advance the material interests of those whom they represent. The claims which you put forward on behalf of experimental research would be wholly unselfish. They would be for work in the common interest, in the interest of mankind. In the report for the year there is a very long list of work done in different departments of scientific research with small sums like 10*l.* or so given out of your small Government grant to meet expenses. It is a list capable of indefinite expansion, and indicates work that might be done on a larger and more fruitful scale. Undertakings like the Research Commission to Uganda may well return their cost a hundred-fold, and I venture to suggest that an appeal should be made to those in charge of the Development Fund to give a wider scope to your disinterested and most beneficent activities."

COTTON GROWING WITHIN THE BRITISH EMPIRE.

THE British Cotton Growing Association was inaugurated in 1902 with the object of extending the cultivation of cotton throughout parts of the British Empire where conditions should prove suitable. During the eight years that have elapsed, valuable information has been acquired by means of pioneering expeditions and experimental cultivation in more remote parts of the Empire and from the results yielded by private undertakings that have been liberally assisted with technical advice and financial means. As it was announced a year ago, the inquiry stage is practically completed, and it has been decided to concentrate the main efforts of the association on the work in Nigeria, Uganda, Nyasaland, and the West Indies. The present state and future outlook of the cotton industry are therefore opportunely summarised in the address delivered by Mr. J. H. Reed before the Royal Geographical Society on Monday, December 5.

The principal supply of raw material from the United States of America has increased during the last quarter of a century from seven to thirteen million bales per annum; the output of India may reach a total of five million bales, but most of it is short-stapled, and Egypt supplies somewhat more than a million bales. Against this has to be placed the demand for cotton, which in this country has remained nearly stationary, at a total of three million bales, while the United States of America now require nearly five million bales, and the countries of Europe absorb six million bales. With regard to other sources of supply, the class of cotton grown in the West Indies is of good quality, but owing to the limited area the amount produced can never be large, so that the most hopeful fields for the labours of the association lie in West and Central Africa. The colony of Lagos bids fair to produce an appreciable quantity of cotton; the extension of the industry in Nyasaland, where a superior type of upland is a prominent variety, is distinctly encouraging, and the late High Commissioner of Uganda has reported upon the favourable climate and conditions, as well as the eagerness of the natives in that Protectorate for taking up cotton cultivation. In the Sudan there are large areas of suitable land near the junctions of the Atbara and the Blue Nile with the main stream, in the province of Berber, and on the plains between the converging courses of the Blue and White Nile. Of the prospects in Rhodesia it is too early to pronounce a definite opinion, but the experimental work gives promise of the possibility of a native industry being developed under European guidance.

PESTS OF FRUIT TREES.

A FRUIT-GROWERS' conference was held, in conjunction with the National Fruit-growers' Federation, at Wye College, Kent, on December 2. Nearly six hundred persons, mostly fruit-growers in Kent, attended. The papers of scientific interest were read by Mr. F. V. Theobald, vice-principal and entomologist at the college, and by Mr. E. S. Salmon, mycologist.

Mr. Theobald dealt with the damage done to fruit trees by Thrips. At least three species of Thrips damage fruit trees and bushes, the commonest, apparently, being *Euthrips pyri*, Daniel. This species is found on apple, pear, plum, raspberry, loganberry, and strawberry. The winged adult females first enter the opening buds, and then by means of their conical mouths so lacerate the young tissue that the buds die soon after opening. Leaves and blossoms are also attacked. The ova are laid in slits cut by the female in the young leaves and strigs. The pale, wingless larvæ attack the young fruitlets, which either crack and drop off prematurely, or, if less injury is done on somewhat larger fruitlets, the abrasions lead to the formation of areas or scars, which disfigure or even entirely ruin the fruit. The larvæ when mature enter the soil, and there produce a pupal stage with long wing buds, and the winged Thrips appear again. The winter is passed in the larval stage in the earth. Treatment with soil fungicides appears to be the only practicable method of dealing with this fruit pest.

Mr. E. S. Salmon dealt with the epidemic outbreak of *Eutypella prunastri*, which during the past few years has destroyed thousands of young fruit trees in certain districts in Kent, Herefordshire, and Worcestershire. In one case near Canterbury 1200 "Victoria" plums, 300 "Czars," and 50 "Monarchs" were attacked and killed. The variety of plum called "Rivers Early Prolific" appears to possess powers of resistance to Eutypella. Young apple and cherry trees have also been destroyed by this disease.

The life-history of the apple "scab" fungus (*Venturia inaequalis*) was dealt with, and instances were given which showed that this disease can be successfully prevented by the use of the fungicide known as "Bordeaux mixture." The statement sometimes made by growers that the "scab" fungus can infect and spread on stored apples is due to an error of identification. Recent investigations made by Mr. Salmon show that we have in this country a species of Leptothyrium, not hitherto reported, which attacks apples both on the tree and in the fruit-room, and forms sooty-looking spots on them. It is probably the species *L. pomi*, well known in America as the cause of the "sooty blotch" and "fly speck" diseases.

Evidence was adduced as to the different degrees of susceptibility to injury from Bordeaux mixture shown by different varieties of English apples.

THE DISCOVERY OF NEPTUNE. LEVERRIER'S LETTER TO GALLE.

WHILE so much has been written about the dramatic discovery of the outermost known planet, it is strange that until quite recently the full text of the letter in which Leverrier announced to Galle the results of his wonderful investigations appears not to have been published.

A copy of this historic document was communicated by its recipient to Dr. See about five years ago, for use in a work on the planetary system which the latter was then preparing. But the death of Galle in July last has prompted Dr. See to anticipate the issue of his work by publishing the letter by itself in No. 8, vol. xviii., of *Popular Astronomy* (October, p. 475). The ostensible reason for writing to Galle was to acknowledge the receipt of the memoir which the latter had prepared, and in which he had reduced and critically discussed Roemer's synopsis of three days' work, which alone escaped the conflagration of 1728, under the title "O. Roemer's Triduum Observatorium Astronomicarum a. 1706 Institutorum" (Berlin, 1845). The letter runs as follows:—

"*Paris, le* 18 *septembre* 1846.

"MONSIEUR

"J'ai lu avec beaucoup d'intérêt et d'attention la réduction des observations de Roemer, dont Vous avez bien voulu m'envoyer un exemplaire. La parfaite lucidité de Vos explications, la complète rigueur des résultats que Vous nous donnez, sont au niveau de ce que nous devions attendre d'un aussi habile astronome. Plus tard, Monsieur, je Vous demanderai la permission de revenir sur plusieurs points qui m'ont intéressé, et en particulier sur les observations de Mercure qui y sont renfermées. Aujourd'hui, je voudrais obtenir de l'infatigable observateur qu'il voulût bien consacrer quelques instants à l'examen d'une région du Ciel, où il peut rester une Planète à découvrir. C'est la théorie d'Uranus qui m'a

conduit à ce résultat. Il va paraître un extrait de mes recherches dans les *Ast. Nach.* J'aurais donc pu, Monsieur, me dispenser de Vous en écrire, si je n'avais eu à remplir le devoir de Vous remercier pour l'intéressant ouvrage que Vous m'avez adressé.

"Vous verrez, Monsieur, que je démontre qu'on ne peut satisfaire aux observations d'Uranus qu'en introduisant l'action d'une nouvelle Planète, jusqu'ici inconnue: et ce qui est remarquable, il n'y a dans l'écliptique qu'une seule position qui puisse être attribuée à cette Planète perturbatrice. Voici les éléments de l'orbite que j'assigne à cet astre :

Demi-grand axe de l'orbite	36,154
Durée de la révolution sidérale	217 ans,387
Excentricité	0,10761
Longitude du périhélie	284° 45′
Longitude moyenne : 1er janvier 1847	318° 47′
Masse	$\frac{1}{9300}$
Longitude héliocentrique vraie au 1er janvier 1847	326° 32′
Distance au Soleil	33,06

"La position actuelle de cet astre montre que nous sommes actuellement, et que nous serons encore, pendant plusieurs mois, dans des conditions favorables pour le découvrir.

"D'ailleurs, la grandeur de sa masse permet de conclure que la grandeur de son diamètre apparent est de plus de 3″ sexagésimales. Ce diamètre est tout-à-fait de nature à être distingué, dans les bonnes lunettes, du diamètre fictif que diverses aberrations donnent aux étoiles.

"Recevez, Monsieur, l'assurance de la haute considération de Votre dévoué serviteur

"U.-J. LE VERRIER.

"Veuillez faire agréer à Mr. Encke, bien que je n'aye pas l'honneur d'être connu de lui, l'hommage de mon profond respect.

"A Monsieur J. GALLE,
"Astronome à l'Observatoire Royal de
"Berlin, à Berlin."

THE NEW ZEALAND SURVEY.

IN a report which has recently been published, the Surveyor-General of New Zealand describes the work of his department during the year 1909–10. A large area of country has been surveyed, but the urgency for pushing forward the topographical and settlement surveys, and the survey of native lands, leaves little opportunity for dealing with the major triangulation of the country. It is satisfactory, however, to see that besides some 320 square miles of minor triangulation, a commencement of a secondary triangulation has been made, and a base-line some eight miles in length has been measured. There is said to be a pressing need for this form of control, which may "bring into harmony different groups of practically uncontrolled minor work with their different standards of length, &c." The experience of many other regions goes to show that not only is such control indispensable, but adequate expenditure on it is the best economy, and very soon repays itself.

As the report is arranged by districts, it is difficult to appreciate fully the character of work done; but the demand for land surveys on large scales is very large, and the want of ample and accurate triangulation of second- as well as the present third-order series is no doubt a real one.

The measurement of a base of the secondary triangulation at Wairarapa was carried out with two five-chain invar tapes; a third of greater width, a quarter of an inch instead of an eighth, was also used for the first two sections only. The tension was determined by a Salter spring balance, and not by weights, as is now the more usual method. The tapes were supported at intervals of fifty links by special stands. Four measurements were made of all sections, two with each tape, and of the first four two additional measurements were made; the probable error of the final value adopted for the base is given as 1 part in 2,962,000. The standard of length for controlling the invar tapes was a steel 100-link tape, of which the true length was known at 62° F. and under a tension of 15 lb., but not its coefficient of expansion and modulus of elasticity. A second base is now in hand, and with the increase of this important high-grade work greater facilities for comparison and verification of base apparatus will doubtless be introduced. The work of the department also includes the harmonic analysis of the tidal observations of the Dominion for the New Zealand Nautical Almanac, and arrangements have been made to furnish advance proofs to the Admiralty.

The work of the magnetic observatory has provided an unbroken series of magnetograms from the Adie instruments, and also a large number of seismograms from the Milne seismographs.

THE JAPAN MAGAZINE.[1]

THE great development of Western education in Japan has naturally led to the extensive publication of newspapers and magazines of a very varied kind, and many of them are of a high literary, scientific, or philosophical quality. *The Japan Magazine* is one of the most recent additions, and although its editor seems to be a European, almost all the writers are Japanese. The issue for October, which has just come to hand, is a very good combination of readable matter, which at the same time is of great interest to all who know Japan.

The first article is on "Torii," the characteristic and picturesque gateways to be found at the entrance to every Shinto shrine. It is one of the best which we have seen, and is illustrated by some of the most striking examples in the country. Mr. Seiichi Tejima, the director of the Higher Technological School in Tokyo, gives an interesting description of the organisation and work of his school which will be read with advantage by those engaged in similar work in this country. In addition to the technical part of the curriculum, the importance which is given to the training of character should be specially noted. Mr. Tejima points out that a person engaged in any occupation may be tempted to bargain his honour for venal purposes if the basis of his morals is not sound, and thereby lose the credit of an expert, and it is therefore the school's principal line of policy in education to give moral training on one hand and engineering practice on the other. Mr. Tejima was recently in London in connection with the Japan-British Exhibition, and no doubt some of our readers made his acquaintance and admired the exhibit shown by his school and other educational institutions in Japan. Viscount Taneko, the well-known statesman and writer, gives some readable reminiscences of American statesmen which throw interesting sidelights on some of the problems arising between America and the Far East.

The chief city engineer of Tokyo, Mr. Benjiro Kusakabe, has a descriptive article on "The New Tokyo," which gives a good idea of the transformation which has taken place and almost made the city unrecognisable by those who knew it in former times. Of course this magic transformation is, after all, not so marvellous as it appears, for the reconstruction of a city of wood cannot be regarded as so colossal a task as would be the rebuilding of a stone city like London or Berlin. But the story of the modernisation of Tokyo is none the less interesting as an indication of the tact, skill, and expedition with which the Japanese attempt and achieve great things, and Mr. Kusakabe thinks that when all the new buildings now either in course of construction or contemplated in the near future are completed, and the city's plan of public improvements carried out, Tokyo will be, both in appearance and reality, one of the finest capitals in the world.

Mr. Yaichi Haga tells "How Western Civilisation came to Japan," and Mr. Yoso Kubo, of the Investigation Bureau, has an important article on "The Remaking of Manchuria," which explains Japanese policy and methods in that part of the world. There are very good articles on "The Art of Judo," or of physical training, with special relation to its ethical aspects, on the "Silk Indus-

[1] Published by the Japan Magazine Co., Tokyo. Subscription, in Japanese Empire, per year in advance, 4.50 yen, in foreign countries 6.100 yen.

try," on "Fruit Culture in Japan," and on "The Art of Flower Arrangement," as well as others of special interest to all who study things Japanese. Altogether, the magazine makes very good reading, and if it maintains the standard of the issue which we have been considering it will take a high place among publications on the Far East.

H. D.

RADIATION FROM HEATED GASES.[1]

On the Radiation from Gases.

IN the first and second reports of the committee reference was made to the part played by radiation in the cooling of the products of an explosion, and to its bearing on the measurements of volumetric and specific heat with which those reports were principally concerned. The general question of radiation from heated gases has, however, from the point of view of the committee, an interest and importance of its own which are sufficient to justify a detailed study of it in its wider aspects. Radiation plays a part comparable with that of conduction in determining the heat-flow from the gas to the cylinder walls in the gas engine, and it is this flow of heat which is the most important peculiarity of the gas engine, and to which are chiefly due the leading characteristics of its design. Even to the uninstructed eye the most obvious features about large internal-combustion engines are the arrangements for cooling, and the great size and weight for a given power which is necessitated mainly by those arrangements. The difficulties which the designer has to meet are due in the main to the stresses set up by the temperature gradients which are necessary to sustain the flow of heat. In the present state of the art it is probable that the most important service which science could render to the gas-engine constructor would be to establish definitely the principles upon which depends the heat-flow from hot gases into cold metal with which they are in contact, and thus to enable him to predict the effect upon heat-flow of changes in the temperature, density, or composition of the charge, and in the state of the cylinder walls.

The committee does not propose in this report to deal with the whole of this large question, but will confine its attention to one important factor in heat-flow, namely, radiation. The subject is a wide one, which has excited much attention among physicists and chemists, and on several important points agreement has not yet been reached. No attempt will therefore be made to do more than state shortly the experimental facts, and to define the issues which have been raised in regard to the explanation of these facts.

Practical Effects of Radiation.

It is believed that the first instance in which radiation from a flame was used in an industrial process, with knowledge of its importance, was the regenerative glass furnace of Frederick Siemens, which he described at the Iron and Steel Institute in 1884. Here the combustible gas was burnt in a separate chamber, and the hot products of combustion were led into the furnace. The objects to be heated were placed on the floor of the furnace out of contact with the stream of flame which flowed above them. They would therefore receive heat only by radiation, and it was supposed that this radiation came in a large measure from the flame. Siemens, however, was of opinion (in 1884) that the radiation was due to incandescent particles of carbon, and that there was little radiation from a non-luminous flame.[2]

In 1890 Robert von Helmholtz measured the radiation from a non-luminous coal-gas flame 6 mm. diameter, and found it to be about 5 per cent. of the heat of combustion.[3] The radiation from a luminous flame was greater, but not very much greater—rising to a maximum of $11\frac{1}{2}$ per cent. for an ethylene flame. Discussing the Siemens furnace in the light of these results, R. von Helmholtz calculated that radiation from the flame in the furnace could only account for a small fraction of the actual heat transmission. He pointed out, however, that a large flame would probably radiate energy at a greater rate than a small one. But while admitting that for this reason gaseous radiation might play a part in the heat transmission, he suggested that a more important agent was radiation from the roof of the furnace, which received heat by direct contact with the hot gas, and so reached a very high temperature. He showed by calculation that a comparatively small excess of temperature in the roof over that of the floor would cause a sufficient flow of heat.

[1] From the Third Report of the British Association Committee, consisting of Sir W. H. Preece (Chairman), Mr. Dugald Clerk and Prof. Bertram Hopkinson (Joint Secretaries), Profs. Bone, Burstall, Callendar, Coker, Dalby, and Dixon, Dr. Glazebrook, Profs. Petavel, Smithells, and Watson, Dr. Harker, Lieut.-Col. Holden, Capt. Sankey and Mr. D. L. Chapman, appointed for the Investigation of Gaseous Explosions, with special reference to Temperature. Presented at the Sheffield meeting of the Association, 1910.

[2] Capt. Sankey has prepared an abstract of papers relating to the Siemens furnace.

[3] "Die Licht- und Wärmestrahlung verbrennender Gase," Robert von Helmholtz. (Berlin, 1890.)

But though the discussions on the Siemens furnace and the work of Helmholtz show that the idea that a flame, even if non-luminous, might radiate large amounts of heat, was a familiar one to many people twenty years ago, its possible importance in causing loss of heat during and after a gaseous explosion, and in determining the heat-flow in a gas engine, does not appear to have been appreciated until quite recently. Prof. Callendar was probably the first to direct attention to its significance in this connection. In the discussion on a paper about explosions, read before the Royal Society in 1906, he said that he had found a non-luminous Bunsen flame to radiate 15 to 20 per cent. of its heat of combustion, and expressed the opinion that the loss from this cause in a closed-vessel explosion would be of the same order.[1]

There are, in fact, several points about the behaviour of gas engines which suggest the importance of radiation as a cooling agent. The particular matter which attracted Callendar's attention was the effect of speed on thermal efficiency. His experiments showed that a part of the loss of efficiency in an internal-combustion motor, as compared with the corresponding air-cycle, was independent of the speed at which the engine was run. The loss of heat per cycle could, to a first approximation, be represented by an expression of the type $A+B/n$, where n is the number of revolutions per minute and A and B are constants. The term A represents a constant loss of heat per explosion, and among the many causes contributing to this constant loss of heat, radiation from the flame is probably important.[2]

Another phenomenon which is difficult to explain, except as the result of radiation, is the effect of strength of mixture on heat-loss. The following table shows some results which were obtained by Hopkinson upon a 40 horse-power gas engine[3]:—

Percentage of gas in cylinder contents	8·5	11·0 per cent.
Total heat-loss per minute	1510	2300 B.Th.U.
Total heat-loss as percentage of total heat-supply	29	34 per cent.
Temperature of piston	300° C.	430° C.

It will be observed that the proportion of heat-loss to the walls increases very materially as the strength of mixture is increased. If the transfer of heat were wholly due to conduction it might be expected, apart from the disturbing influence of speed of ignition, which in this case was not very important, that the percentage of heat-loss would rather diminish with increase of charge, because the temperature with the stronger mixture should be relatively less on account of the increase of volumetric heat. The increased temperature of piston and valves would work in the same direction. The existence of radiation, however, which increases more rapidly in proportion to the temperature, would account for the increased heat-flow. The practical importance of questions of this kind is illustrated by these figures, from which it appears that the piston is 50 per cent. hotter, though the charge of gas is only increased 30 per cent.

More direct evidence of the importance of radiation is furnished by experiments on the effect of the surface of the walls. In the second report of the committee reference was made to the belief, which is widely spread among those who are concerned with the practical design and operation of gas engines that polishing the interior of the

[2] Proc. Inst. Automobile Eng., June, 1907.
[3] Proc. Inst. C.E., vol. clxxvii. (1909).

combustion chamber tends to increase efficiency. Some experiments were also quoted in which it was found that lining an explosion vessel with bright tinfoil perceptibly retarded the cooling of the products. More recently an explosion vessel has been plated with silver on the inner surface, and the results have been compared after exploding identical mixtures, first when the lining was highly polished, and secondly when it was blackened over with lamp-black. It was found that by highly polishing the interior of the vessel the maximum pressure reached could be increased 3 per cent., and the subsequent rate of cooling during its earlier stages reduced by about one-third. These experiments leave no doubt of the reality and of the practical importance of radiation as a factor in determining the heat-loss in the gas engine.[1]

Reference may also be made to the part played by radiation in determining the heat-flow in a boiler. Attention was directed to this by Dalby in a recent report to the Institution of Mechanical Engineers.[2] The circumstances in this case are widely different from those usually obtaining in the gas engine, but the instance serves to emphasise the importance to the engineer of the questions which will be discussed in this report.

Amount of the Radiation from Flame.

R. von Helmholtz appears to have been the first to attempt the accurate measurement of the radiation emitted by a flame. He found that a "solid" flame 6 mm. diameter, burning coal-gas, radiated about 5 per cent. of the total heat of combustion. A carbon monoxide flame radiated about 8 per cent., and a hydrogen flame about 3 per cent. On account of the smallness of the flame his experiments have not much application to the problem of the gas engine. The size of the flame affects the matter in two ways. In the first place, a large flame radiates more per unit of area than a small one, because a flame is to a great extent transparent even to its own radiation, so that radiation is received, not only from molecules at the surface of the flame, but also from those at a depth within it. This matter will be further dealt with in another section of the report. The second point is that the cooling of the gas is slower in a large flame than in a small one. The radiation originates in the vibration of the CO_2 and steam molecules, and the life of one of these molecules as a radiating body extends from the moment of its formation to the time when its vibrational energy has been destroyed by radiation and by collision with colder molecules, such as those of the air surrounding the flame. The smaller the flame the more rapid will be the extinction of the vibrations, and the less, therefore, the total amount of radiation per molecule. The products of explosion in a closed vessel or in a gas engine differ considerably in this respect from any open flame, however large, which it is possible to produce, for they are not subject to cooling by mixture with the outside air. Moreover, the density of the gas is very much greater.

Callendar has repeated some of Helmholtz's experiments on a larger scale, and has found that the radiation in a non-luminous coal-gas flame 30 mm. in diameter may amount to 15 per cent. of the whole heat of combustion. Further reference will be made to Callendar's work under the heading of "transparency."

Hopkinson has recently made measurements of the radiation emitted in the course of an explosion in a closed vessel and subsequent cooling. A bolometer made of blackened platinum strip was placed outside a window of fluorite in the walls of the explosion vessel. The electrical resistance of this bolometer was recorded by means of a reflecting galvanometer throwing a spot of light on a revolving drum, and an optical indicator traced simultaneously a record of the pressure on the same drum. He found that the total heat radiated during an explosion of a 15 per cent. mixture of coal-gas and air, and the subsequent cooling, amounted to more than 22 per cent. of the whole heat of combustion. The radiation which had been received at the moment of maximum pressure amounted to 3 per cent., and it continued, though at a diminishing rate, for a long period. Radiation was still

[1] Hopkinson, Proc. Roy. Soc., A., vol. lxxxiv. (1910), p. 155.
[2] Proc. Inst. Mech. Eng, October (1909).

perceptible half a second after maximum pressure, when the gas-temperature had fallen to 1000° C.[1]

Nature and Origin of the Radiation from Flames.

In the gas-engine cylinder and in explosion experiments we are usually concerned with flames in which there is some excess of air. A mixture of similar composition burnt at atmospheric pressure would give an almost non-luminous flame; in the gas engine there is more luminosity on account of the greater density. There is, however, no reason to suppose that the radiation in the gas-engine cylinder differs materially as regards its quality or origin from that emitted by an open flame.

A very complete analysis of the radiation from different kinds of flame was made by Julius, and his experiments leave no doubt that the radiation is almost wholly due to the CO_2 and steam molecules. He examined the spectrum of the flame by means of a rock-salt prism, and he found that in all flames producing both CO_2 and steam most of the radiation was concentrated into two bands, the wave-lengths of which are, respectively, $4 \cdot 4\ \mu$ and $2 \cdot 8\ \mu$. In a pure hydrogen flame the 4·4 band disappears completely, but the other remains; and in the pure CO flame the 2·8 band disappears, the other remaining. These results are independent of the nature of the combustible gas, the spectrum depending solely on the products of combustion.[2]

A confirmation of the statement that the radiation from these flames originates in the CO_2 and H_2O molecules only was furnished in the course of the work by R. von Helmholtz, to which reference has been made above. He measured the amount of radiation per litre of gas consumed, emitted by flames of given size burning, respectively, hydrogen, carbon monoxide, and certain compound gases, such as methane, giving both CO_2 and steam. The supply of air was adjusted in each case so that the flame was just non-luminous. His results are best given in his own words, but it should be stated that he worked with a small flame about 6 mm. diameter and measured the radiation with a bolometer, taking the steady change of its resistance as a measure of the amount of radiation falling upon it:—

"According to the experiments of Julius described in the first chapter, the *quality* of the radiation of flames depends only on the nature of the burnt and not on that of the burning gases. It is relevant to inquire whether the *quantity* of radiation is also dependent on the mass of the products of combustion. I have calculated in the second and third columns below how many litres of H_2O and CO_2, respectively, arise theoretically from each litre of combustible gas. I then assume that for every litre of water produced as much radiation is sent out as corresponds to the radiating power of a hydrogen flame—for this gas yields one litre of H_2O per litre of combustile—and that in a corresponding way the radiation from one litre of carbonic acid would be determined by the radiating power of the carbonic oxide flame, and I can then calculate the radiation from the non-luminous flames of methane, ethylene, and coal-gas.

	Litres		F	
	H_2O	CO_2	Observed	Calculated
Hydrogen	1	0	74	—
Carbon monoxide ..	0	1	177	—
Marsh gas	2	1	327	325
Ethylene	2	2	510	502
Coal gas...	1·2	0·5	181	179

"The correspondence between the calculated numbers with the radiation from a flame which has just been rendered non-luminous surprised me the more since the latter is conditioned, in some measure, by the volume of air mixed with the gas, and this is very different for the three non-luminous flames. On this account it cannot be asserted that this agreement is not accidental. Moreover, the number of observations is much too small. Nevertheless, the experiment seems worthy of record and will be followed up further."

[1] Proc. Roy. Soc., A., vol. lxxxiv. (1910), p. 155.
[2] "Die Licht- und Wärmestrahlung verbrannter Gase," Dr. W. H. Julius. (Berlin, 1890.)

With regard to the last remarks, it is to be noted that the fact that the flame was just rendered non-luminous shows that the air was in each case in approximately the proportion required for complete combustion. The heating value of such a mixture is much the same for all the gases in the above table, and the temperatures of the flames would be still more nearly the same, the higher heating value of a CO mixture being partly neutralised by the high specific heat of the products. The agreement is certainly more than a coincidence. W. T. David, from a comparison of the radiation emitted in the steam and CO bands, respectively, in a coal-gas and air explosion, infers that CO_2 radiates about $2\frac{1}{2}$ times as much as steam per unit of volume. This result, which was obtained in ignorance of Helmholtz's estimate, agrees with it almost exactly.

Cold CO_2 shows a strong absorption band at the same point of the spectrum as the emission band given by a flame in which CO_2 is produced, and water vapour powerfully absorbs the radiation from a hydrogen flame.

As stated above, it is most probable that the radiation in an explosion also consists almost entirely of the same two bands as are emitted by the Bunsen flame. A complete analysis of the radiation from an explosion has not been made, but Hopkinson and David found, using a recording bolometer, that the radiation is almost completely stopped by a water-cell, and that it is largely stopped by a glass plate. It follows that the luminosity of the flame in an explosion or in a gas engine accounts for but little of the energy which it radiates.

Molecular Theory of Radiation from Gases.

Much difference of opinion exists as to the physical interpretation of the facts described in the preceding sections. The issues in this controversy can conveniently be stated in terms of the molecular theory, and it is therefore desirable to give a short account of this theory. But it will be apparent that the issues are not merely of theoretical interest, but are in large measure issues of fact capable of being tested by experiment, and that the answers to important practical questions may depend on the manner in which they are settled.

According to the kinetic theory, the energy of a gas must be referred partly to translational motion of the molecules as a whole and partly to motions of some sort internal to the molecules. The translational motion is that which causes the pressure of the gas, and in the case of gases for which pv/θ is constant (with which alone we are concerned in this discussion), the translational energy per unit of volume is equal in absolute measure to $1\frac{1}{2}$ times the pressure. This part of the energy may conveniently be called "pressure energy." It amounts to nearly 3 calories per gram molecule, or to 12 feet lb. per cubic foot per degree centigrade.

The other part of the energy produces no external physical effect except radiation, and at ordinary temperatures, when there is no radiation, its existence and amount are inferred from the fact that when work is done or heat put into the gas the corresponding increase in pressure energy amounts to only a fraction of the whole. The internal motions to which this suppressed energy corresponds may be pictured as of a mechanical nature, such as the vibrations of spring-connected masses or as rotation about the centre of gravity of the molecule, but there is not the same reason as exists in the case of the translational energy for supposing that they are really of this character. They may be, and indeed probably are, electrical phenomena, at any rate in part. Any radiation from the gas must take its origin in this internal motion, and so much of that motion as gives rise to radiation must be of a periodic character and have a frequency equal to that of the radiation emitted. It will be convenient to call the whole energy which is internal to the molecule "atomic energy," and that part of it which gives rise to radiation may be called "vibrational energy." The vibrational energy may be imagined as due to high-frequency vibrations within the molecule, and the rest of the atomic energy as due to slower movements—perhaps rotations of the molecule as a whole—which do not produce any disturbance in the æther. This remaining energy may conveniently be called "rotational," it being understood that the motion to which it corresponds is not necessarily a physical rotation, but is some internal motion which gives no external physical effects.

When the gas is in a steady state the various kinds of energy will bear definite ratios to one another, dependent on the temperature and pressure. It may be expected, however, that after any sudden change of temperature or pressure the gas will not at once reach the steady state of equilibrium corresponding to the new conditions. For instance, it may be that in the rapid compression of a gas the work done goes at first mainly to increasing the translational energy. If in such case the compression be arrested, and if there be no loss of heat, this form of energy will be found in excess; and a certain time, though possibly a very short time, will elapse before the excess is transformed by collisions into atomic energy and the state of equilibrium attained. This change would be manifest as a fall of temperature or of pressure without any change of energy.

If, on the other hand, the gas be heated by combustion, the first effect is undoubtedly an increase in the energy of those molecules, and of those only which have been formed as the result of the combustion; and it is probable that in the first instance the energy of the newly formed molecules is mainly in the atomic form. Before equilibrium can be attained there must be a process of adjustment, in the course of which the energy of the new molecules will be shared in part, with inert molecules, *e.g.* the nitrogen in an air-gas explosion, while the translational form of energy will increase at the expense of the atomic energy. The final state of equilibrium reached will be the same at the same temperature, whether the gas was heated in the first instance by combustion or by compression; the assumption that this is the case is involved in any statement of volumetric heat as a definite physical quantity. The pressure energy in the final state of equilibrium is certainly shared equally between the different kinds of molecules, but the atomic energy is not necessarily equally shared. It is known, for example, that the steam molecules, after an explosion of hydrogen and air, carry, on the average, more energy than the nitrogen molecules, though the pressure energy is the same.

The process of attaining equilibrium after an explosion, which has just been described, would (if heat loss were arrested) result in a rise of temperature, and in the ordinary case of rapid cooling it would retard the cooling. It would, therefore, be indistinguishable as regards pressure or temperature effects from continued combustion or after-burning.

Stated in terms of the molecular theory, the first question as to which there is difference of opinion is whether the radiation from a flame arises from gas which is in equilibrium or whether it comes from molecules which still possess a larger share than they will ultimately (in the equilibrium state) be entitled to of the atomic energy which resulted from their formation. If the products of combustion of a non-luminous Bunsen flame were heated, say, by passing through a hot tube—to the average temperature of the flame (taken to be equal to that of a solid body of moderate extent immersed in it), would they emit substantially the same amount of radiation? In order to clear the ground for the discussion of this question it will be convenient, first, to state two or three points about which there will probably be general agreement. First, there is here no question of the origin of luminosity, for the luminous part of the radiation from the flame possesses practically no energy. Secondly, the radiation, whether in the heated gas or in the flame, arises almost entirely from the compound constituents CO_2 and H_2O; in neither case does any come from the molecules of nitrogen or of excess oxygen. And, thirdly, the powerful absorption of cold CO_2 for the radiation from a CO flame, and of water vapour for that from a hydrogen flame, will probably lead all to admit that these gases when heated will emit *some* radiation of the same type. The only question is, how much?

R. von Helmholtz was of opinion that the radiation in a flame comes mainly from molecules which have just been formed, and which are, therefore, still in a state of vigorous vibration. Pringsheim, Smithells, and others take the same view. This is practically equivalent to saying that this radiation, like the radiation of higher

frequency which gives luminosity, is due to chemical action and not to purely thermal causes. On the other hand, Paschen and some others have maintained that the radiation from a flame is purely thermal, or that it arises from gas which has attained the normal or equilibrium state, and is substantially the same as that which would be emitted if the products of combustion were heated.

It will readily be seen that the difference between the two opinions really turns on the question of the time taken by a gas which is not initially in, or has been disturbed from, the equilibrium state to attain that state. All will concede that the CO_2 or steam molecule will radiate more powerfully just after its formation than at any other time. If, as R. von Helmholtz contended, the greater part of the radiation which it gives out in the course of its life is to be ascribed to this early period of its history, we must suppose that that period is sufficiently extended to give time for the emission of a considerable amount of energy with a rate of radiation which, though greater than that of the gas in its ultimate equilibrium state, is at least of the same order of magnitude. In other words, we must suppose that the process, which may indifferently be called attainment of equilibrium or continued chemical action, must go on in the gases as they pass through the flame for a time of the order perhaps of one-tenth of a second. For if it be supposed that equilibrium is reached in an excessively short time, say in 1·1000 second or less, then the radiation, if ascribed to that short period, must be supposed to be of corresponding intensity—there must be a sudden and violent flow of energy by radiation just while combustion is going on, and very little radiation after it is complete. This is, however, negatived by the bolometer measurements made during an explosion, which show that radiation goes on for something like half a second after maximum pressure. Those who hold that the radiation emitted by CO_2 and steam is mainly due to continued combustion must be prepared to admit that such combustion goes on for a long period after the attainment of maximum pressure in an explosion. The issue involved here is, in fact, the same as that in the controversy about "after-burning."

The principal argument advanced by R. von Helmholtz in support of his view is the experimental fact discovered by him that the radiation of a flame is diminished by heating the gas and air before they enter the burner, in spite of the fact that the temperature of the flame must be raised. This he explains by the acceleration of the approach to the state of equilibrium which would be brought about by the more frequent collisions between the newly formed compound molecules and their neighbours.

The question of the velocity with which a gas approaches its normal state after a disturbance has been much discussed in connection with the kinetic theory. Immediately after an explosion we have an extreme case of such a disturbance, the atomic energy being, at any point which the flame has just reached, in considerable excess. The transformation of this energy into the pressure form will proceed at a rate diminishing with the amount remaining to be transformed and, in the final stages of the process at all events, proportional thereto. The slowness of approach to the state of equilibrium may be measured by the time required for the reduction of the untransformed energy in any specified ratio. It is usual to take $1/e$ as this ratio, and, following Maxwell, the corresponding time may be called the "time of relaxation." Estimates of this time, based on the kinetic theory of gases, may be made in various ways, but they all involve hypotheses as to the nature of the action between the molecules, and must be regarded as little more than speculation. It will be well, however, to indicate the general character of the arguments on which they are based. By methods which need not be considered in detail here, it is possible to calculate the number of collisions with its neighbours which the average molecule undergoes per second. This calculation can be approached in various ways, based on different kinds of data, but they all lead to the same result, at any rate as regards order of magnitude, namely, that a molecule of air at normal temperature and pressure collides, on the average, 3×10 times per second with other molecules. At every collision the energy distribution in the colliding molecules is modified, both as regards the manner in which it is shared between the two and the relative proportions due to vibration and translation in either. It is argued that after every molecule has suffered a few thousand collisions, which will happen in a millionth of a second, the gas must have reached a steady average state. This argument would, however, be upset if the interchange of energy as between vibration and translation at each collision were sufficiently small. It is only necessary to suppose that a vibrating molecule loses less than one-thousand millionth part of its vibratory energy at each collision to raise the time of relaxation to something of the order of a second. Any objection to this supposition must be founded on some hypothesis, which cannot be other than entirely speculative, as to the mechanism of a collision. The kinetic theory, therefore, can give no information about the absolute value of the time of relaxation, though it provides valuable suggestions as to the way in which that time is affected by the temperature and density of the gas.

There is plenty of physical evidence, however, that in ordinary circumstances the time of relaxation is excessively short. The phenomena of the propagation of sound shows that compressions and rarefactions of atmospheric air may take place many thousands of times in a second without the gas departing appreciably at any instant from the state of equilibrium. The experiments of Tyndall, in which an intermittent beam of radiant energy directed through the gas caused variations of pressure sufficiently rapid to give sounds, show that the transformation of vibrational into pressure energy under the conditions of his experiments is a process far more rapid than any with which we are accustomed to deal in the gas engine or in the study of gaseous explosions. The departure from equilibrium which follows combustion is, however, of a special kind, and it may be that the gas is slower in recovering from it than when the disturbance is that produced by the propagation of sound at ordinary temperatures.

Transparency.

The radiation from hot gas is complicated by the fact that the gas is to a considerable extent transparent to its own radiation. The radiation emitted, therefore, depends upon the thickness of the layer of gas, instead of being purely a surface phenomenon, as in the case of a solid body. This property, besides being of great physical interest, is important from the point of view of the committee because upon it depends, or may depend, the relative magnitude of radiation losses in engines or explosion vessels of different sizes.

The transparency of flames is well illustrated by some experiments which Prof. Callendar has been making, and which he showed to the committee. The radiation from a Mêker burner (which gives a "solid" flame without inner cone) was measured by means of a Fery pyrometer, the reading of which gives a measure of the radiation transmitted through a small cone intersecting the flame and having its vertex at this point of observation (see Fig. 1). Callendar proposes to give the name "intrinsic radiance" to the radiation of a flame measured in this way, divided by the solid angle of the cone. When a second similar flame was placed behind the first in the line of sight, it was found that the reading recorded by the pyrometer was considerably increased, but not doubled; the first flame appeared to be partly, but not completely, transparent to the radiation emitted by the second. A third flame placed behind the first two contributed a further but smaller addition to the radiation, and as the number of flames in the row was increased the radiation received from each fell off according to an exponential law. The total radiation from the whole row (which is that recorded on the pyrometer) tends to a finite limit as the number of flames is increased. The radiation from a depth of 12 cm. is about half, and that from a depth of 100 cm. is within half per cent. of that emitted by an infinitely great depth.

The general result of Callendar's experiments is to show that flames of a diameter of 3 centimetres or less burning at atmospheric pressure emit radiation approximately in proportion to the volume. If the diameter be increased beyond that figure the radiation will also increase, but not in proportion to the volume of the flame. The radiation from very large flames would tend to become proportional to the surface, but no certain inference as to the diameter

of flame for which this would be substantially true can be drawn from Callendar's experiments, because he was looking along a thin row of flames in which there was but little lateral extension.

The flames met with in a gas-engine cylinder or in explosion vessels differ from open flames such as can readily be produced in the laboratory, both in respect of the lateral extension which has just been mentioned and also in respect of density. In both these particulars the difference is rather great, the least dimension of the mass of flame in a gas-engine cylinder being only in the smallest sizes comparable with the diameter of the Mêker burner flame, while the density of the gas just after firing in the gas engine is from twenty to thirty times that of the burner flame gases. It does not seem possible from theoretical considerations to determine the effect of these two factors with sufficient accuracy to enable any quantitative inference as to radiation in the gas engine to be drawn from laboratory experiments on flames, but it is useful to discuss their probable qualitative effects.

In Fig. 1, P is the point of observation at which the pyrometer is placed, as in Callendar's experiments, and the portion of the flame from which the radiation is measured is that intercepted by the small cone. If a second similar flame B is placed behind A at a considerable distance, but so that it is intersected by the cone, then the radiation recorded by the pyrometer will be increased, say, by 50 per cent., showing that of the radiation emitted by B and falling on A 50 per cent. is absorbed and the remainder is transmitted to the pyrometer. The absorbed energy is, of course, not lost, but must result

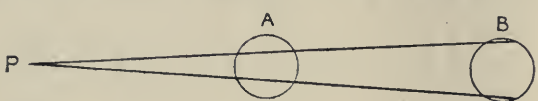

FIG. 1.

FIG. 2.

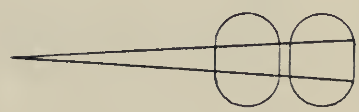

FIG. 3.

in slightly increased radiation from A in all directions. The flame A appears to be a little hotter because of the proximity of B. Thus the increase of radiation absorbed at the pyrometer is due, not only to the radiation transmitted from B, but also to an increase in the intrinsic radiance of A. If the two flames are a considerable distance apart, the latter part is negligibly small, since the flame A does not then receive much radiation from B, and what it does receive is dissipated in every direction. But when flame B is pushed close up to A into the position of B[1] (Fig. 2) this effect may be considerable, and it is obvious that it will be greatly enhanced if the two flames are extended laterally as in Fig. 3. For in such case flame A must get rid of the energy which it is receiving by radiation from B[1], mainly by an enhanced radiation in the direction of P. It may therefore be expected that the effect of lateral extension will be to make the flame apparently more transparent.

To a first approximation it may be expected that the radiating and absorptive powers of a gas at a given temperature will be proportional to its density. That is to say, two geometrically similar masses of flame, in which the temperatures at corresponding points are the same, and the densities in inverse proportion to the volumes (so that the total masses are the same), will radiate in the same way and to the same total amount. It would seem that this must be so, so long as the vibrations of the radiating molecules are the same in character and amplitude in the two cases. For there will then be the same number of molecules vibrating in exactly the same way and arranged in the same way in the two cases. The only difference is in the scale of the arrangement, and this can only affect the matter if the distance between molecules is comparable with the wave-lengths of the radiation emitted, which is not the case. It is only, however, within moderate limits that the molecular vibrations are independent of density. Angström found that the absorption of the radiation from a given source in a tube of CO_2 at ordinary temperature and atmospheric pressure was reduced by increasing the length and diminishing the pressure [1] in the same proportion so as to keep the mass of gas constant. Schäfer found that on increasing the pressure the absorption bands of this gas were widened, so that the curve connecting intensity of radiation and wave-length did not remain of the same shape.[2] These experiments were made at low temperatures, and at the higher temperatures, in which the committee are more particularly interested, there has been but little work. There is no reason to doubt, however, that the character and amount of the radiation from CO_2 and steam at high temperatures will change with the density.

From the point of view of the molecular theory, such a change might be anticipated from either of two causes. An increase of density implies a proportionate increase in the frequency of molecular collisions, and this would result in greater facility of interchange between the translational and atomic types of energy. It is possible that the equilibrium proportion of the two types might be different in consequence. The denser gas may conceivably possess, with a given amount of translational energy, more atomic energy, and therefore radiate more strongly at a given temperature. It is certain that there would be a more rapid attainment of equilibrium in the gas after an explosion or a rapid expansion. Another possible cause is a direct interaction between the molecules, apart from collisions. Two molecules at a sufficient distance apart will vibrate practically independently, each behaving as though the other was not there, except that there will be a tendency for them to vibrate in the same phase. But if the two are close together they react on one another so that the natural period or periods of the two together will not be the same as those which each would have if it were isolated.

Such direct measurements as have been made of the radiation after a closed-vessel explosion suggest that the flame is more transparent than might be inferred from the experiments on open flames. According to information given to the committee by Prof. Hopkinson, W. T. David has found that the radiation received by a bolometer placed outside a fluorite window in the cover of a cylindrical explosion vessel 30 cm. × 30 cm. is greatly increased by highly polishing that portion of the opposite cover which can be "seen" by the bolometer. This implies that a thickness of 30 cm. of flame in these circumstances can transmit much of the radiation which it emits. The density of the gas in this case was atmospheric, and the 30 cm. thickness in the explosion vessel would be equivalent to perhaps 150 cm. of open flame if absorption were simply proportional to density. According to Callendar's experiment, such a thickness would be almost completely opaque. It is possible that the lateral extension is sufficient to account for this result. The open flame should be a cylindrical mass of dimensions 150 cm. × 150 cm., instead of a long strip with a cross-section of 3 cm., in order to make the two cases strictly comparable. It will be remembered that in the discussion above it appeared that the laterally extended flame would seem to be more transparent.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Walsingham medal for 1910 has been awarded to A. V. Hill, of Trinity College. A second medal has been awarded to J. C. F. Fryer, of Gonville and Caius College.

The following have been elected to the Clerk Maxwell scholarship:—R. D. Kleeman and R. T. Beatty, both of Emmanuel College.

At a meeting of the Fitzwilliam Museums syndicate, held

[1] Ark. for Mat. Astron. och Fysik. Stockholm, vol. iv., No. 30, p. 1.
[2] Ann. der Physik, vol. xvi. (1905), p. 93.

on November 29, F. W. Green, of Jesus College, was appointed honorary keeper of the Egyptian antiquities.

OXFORD.—At a Convocation held on December 6, the Vice-Chancellor (Dr. Heberden, Principal of Brasenose) presiding, the honorary degree of doctor of science was conferred on Prof. Meldola, F.R.S., professor of chemistry in the Finsbury Technical College (City and Guilds of London Institute), in anticipation of the Herbert Spencer lecture to be delivered by him on December 8. In making the presentation, the Sedelian professor natural philosophy, Prof. A. E. H. Lowe, F.R.S., delivered the following oration:—

"Adest vir quem omnes, qui scientiae et imprimis Chemiae et Biologiae student, ornare gaudent, Societatis Regalis Sodalis, Societatum Entomologiae, Chemiae, Chemicorum industriae, operam dantium Praeses emeritus, Raphael Meldola. Qui vir cum prima aetate Carolo Darwin coniunctissimus esset, ita de Natura formarum novarum creatrice quaesivit ut plurimis eodem studio incensis illud Biologiae genus quod ipse excoluerat nostratium fere proprium fieret. Posteriora eius studia partim in Physice, partim in Chemia versata sunt, quo e numero si pauca quaedam momenti maximi commemorare liceat, et eligerem quae de Chemia Photographiae inserviente, de chemicis carbonis elementis, de chemica umorum corporalium compositione commentus est. Multos iam annos in hoc Chemiae genere principem habitum atque latissimo in campo evagatum nescio an nemo hunc virum laude superavit."

THE annual prize distribution and students' conversazione of the Northampton Polytechnic Institute, Clerkenwell, E.C., is to be held this evening, December 8. The Right Hon. Lord Alverstone, G.C.M.G., P.C., Lord Chief Justice of England, will distribute the prizes and certificates. Lecturettes will be given by Mr. F. M. Denton on commercial uses of electro-magnets, and Mr. F. Handley Page on how to fly.

DR. EDGAR F. SMITH has been appointed to succeed Dr. C. C. Harrison as provost of the University of Pennsylvania, in which institution he has held a chair of chemistry since 1888. His chief work has been done in electrochemistry, as a list of his principal publications would show. He is a past-president of the American Chemical Society and of the American Philosophical Society. He has also been a member of the U.S. Assay Commission and adviser in chemistry to the Carnegie Institution.

THE annual conversazione of the Royal College of Science and Royal School of Mines will be held on Wednesday, December 21. Both the new and old buildings will be open in Imperial Institute and Exhibition Roads, South Kensington, S.W., and many interesting exhibits will be shown in chemistry, physics, mechanics, metallurgy, mining, botany, and zoology, arranged by the respective scientific societies. During the evening Dr. C. Gilbert Cullis will give a lecture on "Coral Islands."

IT is announced, says *Science*, that Mr. Andrew Carnegie has given a further sum of 300,000*l*. for the construction of buildings of the Carnegie Technical Schools at Pittsburgh. From the same source we learn that by the will of Prof. A. Marshall Elliott the Johns Hopkins University receives his library, and the sum of 400*l*. for the establishment of a scholarship for graduate students; and that the American Museum of Natural History receives 5000*l*. by the will of the late Mr. Charles E. Tilford, of New York City.

STEPS are being taken to inaugurate a Students' Union in connection with Sheffield University. An influential committee, representative of all faculties, has been elected from amongst the members of the Students' Representative Council to proceed with the formation of the union. Sheffield University stands alone amongst the universities of the United Kingdom in not possessing such an institution, and we feel sure that the committee's appeal to members of the University and their friends for contributions to the fund to provide premises where students may be united in the bonds of social intercourse will meet with a generous response. Cheques may be made payable to Mr. H. Khalifa, honorary secretary and treasurer to the Students' Union Committee, The University, Sheffield.

THE Royal Agricultural College, Cirencester, founded in 1845 and reorganised in 1908, is now definitely associated with the University of Bristol for the purpose of instruction in agriculture, forestry, estate management, land surveying, veterinary science, natural history, agricultural chemistry, botany, zoology, and geology, to which other allied subjects may subsequently be added. Instruction given at the college in these subjects to undergraduates will be deemed to be instruction given in and by the University for the purpose of degrees and diplomas in agriculture and forestry. The present principal, Mr. Ainsworth-Davis, is recognised as professor of natural history in the University, and Mr. Drysdale Turner as professor of agriculture, this recognition carrying with it membership of the University Senate. While the association will in no way interfere with the primary work of the Royal Agricultural College, which will still retain its distinctive and time-honoured diploma, a new class of students will come into existence, and an important advance be made in the correlation of agricultural education in the west of England.

UNDER the auspices of the London County Council, another conference of teachers will be held on three days, Thursday, Friday, and Saturday, January 5, 6, and 7, 1911, at Birkbeck College, Bream's Buildings, Chancery Lane, E.C. The programme includes the following subjects, among others:—Thursday, January 5, *Specialisation in Schools:* Addresses by Mrs. Sophie Bryant on the value of specialisation in secondary schools, and F. Bulley on an experiment in specialisation in elementary schools. *Memory:* Addresses by Dr. C. Spearman on the relation of the memory to the will, Dr. E. O. Lewis on some interesting investigations on memory, and Dr. F. H. Hayward on the cultivation of memory. Friday, January 6, *The Teaching of Geography:* Addresses by B. C. Wallis on the teaching of geography in secondary schools, J. Fairgrieve on a practical room for the teaching of geography, and C. J. Rose on open air teaching in geography. Saturday January 7, *Education Experiments in Schools:* Addresses by B. Lewis on a combined scheme of history and geography teaching, E. Thomas on pictorial aids for the teaching of geography and history, A. G. Gawler on how to secure individual work in large classes, J. Greer on an experiment in number teaching, A. E. D. Lowden on stencilling—a valuable form of handwork, and Mrs. Sandford on animals in infants' schools. No charge will be made for admission to the conference. Application for tickets of admission should be made to the Chief Inspector, London County Council, Education Offices, Victoria Embankment, W.C.

BY the passing of the Education (Choice of Employment) Bill into law on the day of dissolution of Parliament, the English and Welsh local education authorities have after a keen controversy been accorded statutory powers to "give boys and girls information, advice, and assistance with respect to the choice of employment." The School Boards of Scotland were put in possession of these powers by the Education (Scotland) Act, 1908, and the School Board of Edinburgh took the lead in making the powers operative. The originator of the conception of a national system of school information and employment bureaux was Mrs. Ogilvie Gordon, D.Sc., who first placed her scheme before the public at the annual meeting of the Glasgow Union of Women Workers, held in March, 1904. The full draft of her scheme was submitted to the President of the Board of Education and to the Secretary for Scotland, and was supported by numerous resolutions passed in its favour at public meetings. It was afterwards published in Mrs. Ogilvie Gordon's "Handbook of Employments" (Aberdeen: Rosemount Press). The aim of the scheme is to bring the teachers' knowledge of the individual boy and girl effectively to bear upon their choice of a future career, and it is based upon the sound economic principle that work on such lines ought to be nationally organised in order to make sure that it should reach every child, and that the work ought to cover all the openings and occupations for our youth—skilled or unskilled, mercantile or personal. By the measure which has at last become law, there is now a prospect of an effective advisory service being organised throughout the country, administered by committees formed under the education authorities, and there should be no difficulty in arrangements being made

locally between the labour exchanges and the education authority, so that no actual overlapping of work shall take place, but each be helpful to the other.

THE annual prize distribution of the Sir John Cass Technical Institute was held on Tuesday, November 29, when Sir William Tilden distributed the prizes and delivered an address; the chair was taken by Sir Owen Roberts, chairman of the governing body. Sir William Tilden, after contrasting the conditions available for obtaining scientific instruction now, in such institutions as that of the Sir John Cass, as compared with his own student days, referred especially to the improved character of the teaching, but pointed out that the responsibility for gaining the full benefit of these advantages rested still, as it did in former years, far more with the students than with the teachers. Whilst the business of the teachers was to be regarded as being concerned with the selection of the subjects to be studied rather than their exposition, the real responsibility for progress must always rest with the student. The assimilation of knowledge is the business of the student, and the greatest inducement and stimulus for such assimilation is the desire for knowledge, a desire which is most advantageously associated with a conviction of ignorance. Sir William Tilden further urged the necessity of the thorough understanding of the subjects taught at each stage of progress, and pointed out that students should not look to their teachers for recipes for doing things, but to their own efforts, as the means of acquiring a full understanding of their work, and that they should not omit becoming fully conversant with the history and meaning of the expressions and words employed in their studies. In conclusion, it was pointed out that with every student there are times when the mind should be allowed to relax a little from the pages of their text-books, and that of the many forms of relaxation it was most desirable that all young English men and women should devote some attention and interest to the history of their own country. The exceptional advantages of London, and especially of the City of London, as a stimulant to such study was particularly referred to, for there is nothing more interesting, more absorbing, or more enchanting than the study of the history of mankind, especially that particular variety of mankind which is represented by the Anglo-Saxon race. Sir William Tilden subsequently opened the new chemistry laboratory which has recently been equipped by the governors of the institute.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 24.—Sir Archibald Geikie, K.C.B., president, followed by Mr. A. B. Kempe, vice-president, in the chair.—Sir Norman **Lockyer**: The sequence of chemical forms in stellar spectra.—A. **Mallock**: Influence of viscosity on the stability of the flow of fluids. The effect of this paper is to direct attention to an observation made by the late Mr. W. Froude, F.R.S., with regard to an experiment on fluid jets, and to its application in explaining some of the phenomena presented by the flow of viscous fluids. The experiment referred to was shown by Froude at the British meeting of the British Association in 1875, and one of the deductions drawn from it was that in a viscous flow the character of the stream differed according as to whether the flow was towards decreasing or increasing pressure.—Horace **Lamb**: Atmospheric oscillations. The paper treats of the free oscillations of an atmosphere, the temperature being a function of the altitude, and the adiabatic laws of expansion being assumed. In particular, the case of a uniform temperature gradient is discussed in some detail. The possible oscillations are of various types, of which the most important is of the character of a longitudinal wave. The results are simplest when the equilibrium state is one of convective equilibrium, and the velocity of the longitudinal wave is then equal to the Newtonian velocity of sound, $\sqrt{(gH)}$, corresponding to the temperature of the lowest stratum. The bearing of the results on Kelvin's theory of the semi-diurnal barometric oscillation is examined, and it appears that the existence of a free period of the earth's atmosphere, of somewhat less than twelve mean solar hours, is highly probable. Other types of oscillation depend for their frequency on the degree of stability of the atmosphere, and may in circumstances be comparatively slow. It is possible that these may account for some of the minor fluctuations of the barometer. The paper includes also an examination of the theory of waves at a surface of discontinuity.—P. J. **Kirkby**: A theory of the chemical action of the electric discharge in electrolytic gas and other gases. The complicated results attending the passage of an electric discharge through electrolytic gas, described in previous papers, and in particular the chemical effects observed in the positive columns of long discharges, were explained by the theory that the chemical action is due to molecular dissociation effected by the collisions of gaseous ions constituting the current with the molecules of the gas, the atoms of which are thus set free to enter into new combinations. In this paper an account is given of experiments designed to determine both the number of molecules of water (w) formed by the passage of the atomic charge through 1 cm. of the positive columns of various discharges passed through electrolytic gas ($2H_2+O_2$), and also the electric force (Y) within these columns, the results providing data for testing and developing the theory. The chemical effects of the positive column are attributed to the motion of the electrons alone. The number of atoms of oxygen set free by the collisions of an electron moving through 1 cm. in electrolytic gas at p mm. pressure under the electric force Y is of the form $cpe^{-bp/Y}$, where c, b are certain constants. Hence, if an atom of oxygen can unite directly with a *molecule* of hydrogen, w is proportional to $cpe^{-bp/Y}$. All the experimental results satisfy this condition within error-limits in the particular form $w/p=7{\cdot}9\,e^{-42{\cdot}7p/Y}$, and thus support the above theory as well as the hypothesis that water-vapour is formed by the collision of an atom of oxygen with a molecule of hydrogen. This equation involves that the energy of formation of an oxygen molecule is less than, and probably nearly equal to, $6{\cdot}\times10^{-12}$ ergs; and experiments of Berthelot upon the heat of transformation of ozone into oxygen are shown to be in fair agreement. An estimate, 7×10^{-12} ergs, is also given for the energy of formation of a molecule of water vapour. These experiments also prove, independently of theory, that dissociated atoms of oxygen are not charged electrically. Similar experiments were made with the gaseous mixture $CO+H_2$. The chemical effects observed in the positive column reproduce the main features observed with electrolytic gas, and are explainable by a similar theory.—G. W. **Walker**: An electrostatic voltmeter for photographic recording of the atmospheric potential. The paper describes some experiments made at Eskdalemuir Observatory with the object of obtaining a simple and efficient voltmeter for continuous photographic registration of the electrical potential at a fixed point in the atmosphere. Experience has shown that occasionally the instrument would require to register up to fully 1000 volts + or −. Satisfactory results have been obtained by means of a Dolezalek electrometer. The usual sensitiveness was greatly reduced by using a phosphor-bronze suspension, while the needle was loaded to prevent tilting. A fixed difference of potential is applied between the quadrants by means of one or two standard cadmium cells, while the potential to be measured is applied to the needle. The needle can now carry 1100 volts with perfect safety and stability, while the scale value on the paper is constant to within a few per cent. over a range from −900 to +900 volts. Trial has been made of a voltmeter (made in the workshop) similar in general design to the Dolezalek, but in which the fixed difference of potential between the quadrants is provided by making the quadrants alternately of copper and zinc soldered together and not insulated. Uniformity of scale value has been obtained from about −500 to +500 volts, but for higher potentials only approximate uniformity was secured. This defect arises from want of mechanical perfection of the quadrants and needle, and should disappear in an instrument made with the same accuracy as the Dolezalek. At present, also, the damping of the needle during very rapid changes of potential is insufficient. Reference is made to certain points in the manipulation of sulphur for insulating, which have been found essential to secure good results.—Dr. T. H. **Havelock**: Optical dispersion: an analysis of its actual dependence upon

physical conditions. The paper is based upon a generalised dispersion formula

$$\frac{1}{\sigma + 1/(n^2 - 1)} \cdot \frac{1}{P} = \Sigma \frac{c_s}{\lambda^2 - \lambda^2_s}$$

where P is the density of the medium. The quantities c_s and λ_s refer to natural vibrations inherent in the molecule, and it is assumed that these are not changed by varying physical conditions, such as temperature, pressure, or density; thus an attempt is made to express these conditions in their optical effect by two variables, P and σ. The scheme is tested first by a relation deduced from the above formula, namely, the difference in value of $P/(n^2-1)$ for any two physical conditions of the same substance is constant in regard to wave-length. From an examination of available data this appears to be satisfied approximately for gases and liquids and for changes from gas to liquid. Numerical values of σ for various substances in different conditions are obtained by assigning it zero value for the gaseous condition at normal pressure and temperature. Artificial double refraction is included in the same formal scheme by allowing anisotropic changes of the quantity σ. Finally, for dispersion formulæ of the above type an observed maximum of absorption (or of selective reflection) is identified, not with λ_s, but with a wave-length λ'_s, differing from λ_s by a term involving P and σ: numerical examples are given for rock-salt and fluorite. The wave-lengths λ'_s are calculated under various conditions for certain substances; experimental data are analysed to show the pressure-displacement for air and the temperature-displacement of absorption maxima for water and carbon disulphide.—C. P. **Butler**: The spectrum of Halley's comet. Provision was made for photographing the comet and its spectrum from the beginning of May at Fosterdown, Caterham. Exceptionally bad weather prevented observations until the end of the month, when photographs and visual observations of the spectrum were obtained on May 23 and 26. The photographs of the comet taken with a Dallmeyer lens, 6 inches aperture, 50 inches focus, show that the nucleus was at times multiple. Visual observations of the nucleus showed strong continuous spectrum with three bands in the yellow-green, green, and greenish-blue, having approximate wave-lengths 5635 (int. 7), 5165 (int. 10), 4737 (int. 7). The spectrum of the coma surrounding the nucleus consisted of these same three bands, without any indication of continuous radiation. The photographic spectra show only the brightest spectra features of the spectrum of the nucleus, the relative intensities differing widely from the visual intensities owing to the selective sensitiveness of the plates. The two most conspicuous bands are near λ 4737 (int. 10) and 3884 (int. 6), with fainter bands near $\lambda\lambda$ 4050, 4360, 5165, and 5635. Photographs obtained elsewhere at different times show differences in the relative intensities of the component bands. This has been ascribed to variations of atmospheric absorption. It may be noted, however, that before and after the transit of May 19 the aspect of the head would vary quickly; at one time the hotter side facing the sun would be best seen, at others the cooler portions away from the sun would be more prominent. Preliminary experiments show that by varying conditions of vaporisation the relative intensities of the carbon or hydrogen bands may be considerably modified, and it would appear that the changes observed in the cometary spectrum might be produced by some such difference of condition.—Dr. H. F. **Baker**: A geometrical proof of the theorem of a double six of straight lines.

EDINBURGH.

Royal Society, November 7.—Prof. Crum Brown, vice-president, in the chair.—J. D. Hamilton **Dickson**: A thermoelectric diagram from $-200°$ to $+100°$ C., based on the experiments of Sir James Dewar and Prof. Fleming. The platinum temperatures were first reduced to absolute scale. The observations of the electromotive force of each metal-lead couple were plotted against temperature, and the curves were drawn freehand with the greatest care through them. By finding the locus of the middle points of parallel chords, Mr. Dickson proved that the curves were all, with one exception, parabolas. The exception was in the case of antimony-lead, for which the curve was a hyperbola. In the majority of cases the parabolas differed from those obtained by Tait through the more limited range of temperature used by him and his students in the main fact that their axes were not perpendicular to the temperature axis. The "Tait lines," as it was convenient to name the lines of thermoelectric power, were not in these straight, although limited portions of them might be very nearly so. As was easily proved from the geometry of the parabola with inclined axis, each Tait line was a curve with two asymptotes perpendicular to one another. Of the metals investigated, gold, silver, zinc, and German silver followed Tait's rule, the thermoelectric powers referred to the lead line giving straight lines; but platinum, copper, cadmium, nickel, manganese, palladium, and aluminium gave for their electromotive-force curves parabolas with inclined axes. Similar results were obtained from recent observations published by Holborn and Wien, Barus, and from early observations by J. Murray and J. C. Young, working under Tait's directions.—Profs. Alex. **Smith** and A. W. C. **Menzies**: A dynamic method for measuring vapour pressures, with its application to benzene and ammonium chloride. A modified form of the isoteniscope, previously described, was used in determining the vapour pressures of these substances. The advantages of the new form of apparatus were that it could be used for high pressures, that the confining fluid could be reduced in amount, and that the thermometer was inserted directly in the bath with its bulb no longer in a region of varying pressure.—Profs. Alex. **Smith** and W. C. **Menzies**: A quantitative study of the constitution of calomel vapour. The object of the investigation was to find to what extent the vapour of calomel was dissociated, and the method was to measure the vapour pressures by means of the isoteniscope at various temperatures from 360° C. to 400° C. The results showed (1) that the vapour of calomel was composed wholly of mercury and corrosive sublimate, HgCl and HgCl being alike absent; (2) that calomel dissolves in mercury with a molecular weight corresponding to the formula HgCl; (3) that the isoteniscope may be used in the quantitative investigation of chemical problems.—Dr. R. A. **Houston**: The efficiency of metallic filament lamps. The results were obtained by means of a new method involving the examination with a thermopile and very sensitive galvanometer of the spectrum of the radiation transmitted by a water filter. The values obtained for the efficiencies of carbon, osmium, tantalum, and tungsten lamps as energy transformers were respectively 2·9, 5·2, 6·5, and 7·5 per cent.

PARIS.

Academy of Sciences, November 21.—M. Émile Picard in the chair.—H. Lorentz was elected a foreign associate in the place of the late Prof. Schiaparelli.—Lord Avebury was elected a correspondant for the section of anatomy and zoology, in the place of Sir Ray Lankester, elected foreign associate.—G. **Fayet**: The identity of the Cerulli comet with the Faye comet. The elements calculated for the two comets are nearly identical, the slight difference noted being probably due to the fact that the considerable disturbance of the orbit of the Faye comet caused by Jupiter in 1899 was only approximately allowed for.—C. **Popovici**: Observation of the Cerulli-Faye comet. Data are given for November 22.—G. **Tzitzéica**: A theorem of M. Darboux.—W. **Stekloff**: A new application of the method of development of fundamental functions.—Paul **Lévy**: The integrability of the equations defining line functions.—G. **Eiffel**: The resistance of rectangular planes struck obliquely by the wind. Experiments were carried out with a suction fan, using a 70 horse-power motor, giving an air current of 10 to 20 metres per second in a tube of 1·5 metres diameter. The results are given graphically in a series of curves.—Jean **Becquerel**: The reversal of the phosphorescence bands. Rubies and an emerald were used for these experiments at the temperature of liquid air. The reversal establishes a qualitative relation between the emission and absorption, and some quantitative relations are worked out.—R. **Jouaust**: The magnetic properties of iron at high frequencies. The iron was used in sheet form, the alternating current, produced by a Poulsen arc, having a frequency of 150,000 per

second. The losses observed are 20 per cent. higher than those calculated from J. J. Thomson's formula.—Frédéric **Reverdin** and Armand **de Luc**: The comparative nitration of mono- and dialkylated amines.—L. H. **Philippe**: The glucodeconic acids. The author has extended E. Fischer's synthesis of gluconose to the next higher homologue, glucodecose. In the present paper the preparation and properties of the glucodeconic acids are described.—G. **Friedel** and F. **Grandjean**: Anisotropic liquids. A discussion of the meaning of some experiments recently described by M. Mauguin on the optical properties of azoxyphenetol. The authors regard the term *anisotropic liquids* as being preferable to *liquid crystals*. Marin **Molliard**: The mode of action of the intensity of illumination in the formation of cleistomamic flowers.—P. A. **Dangeard**: A marine alga from the Concarneau Laboratory.—M. **Ringelmann**: Experiments on the yield of juice from the cider press.—Armand **Dehorne**: The coexistence of division and a subdivision of chromosomes in a quiescent state.—Paul **de Beauchamp**: A new gregarian of the genus Porospora.—A. **Gruvel**: The lampreys of the western coast of Africa and their commercial possibilities.—J. **Chatanay**: A remarkable anomaly of *Zonabris variabilis v. Sturmi*.—A. **Fernbach**: The biological degradation of the carbohydrates. Macerations of *Tyrothrix tenuis* act upon starch, maltose, dextrose, or saccharine, and dioxyacetone, glyceric aldehyde, and methylglyoxal have been recognised among the products of the reaction. Formaldehyde and acetaldehyde are also produced by this organism.—J. **Effront**: The action of the Bulgarian ferment upon proteid and amido substances. The Bulgarian ferment rapidly destroys albuminoid material, removing the nitrogen in the form of ammonia, and it is possible that the favourable action of the ferment in gastro-intestinal affections is due to this action instead of to the production of lactic acid.—P. **Chaussée**: The production of primitive thoracic tuberculosis in cattle by the inhalation of infinitesimal amounts of bovine tuberculous material. These experiments prove the possibility of direct infection of the lungs by the inhalation of minute proportions of tuberculous material. In all the cases the mesenteric and cervical ganglia were examined for tubercular infection with negative results.—Jacques **Deprat**: Seismic activity in southern Yun-nan in 1909.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 8.

ROYAL SOCIETY, at 4.30.—Colour-blindness and the Trichromatic Theory. Part II. Incomplete Red or Green Blindness: Sir W. de W. Abney, K.C.B., F.R.S.—On the Sensibility of the Eye to Variations of Wavelength in the Yellow Region of the Spectrum: Lord Rayleigh, O.M., F.R.S.—(1) Trypanosome Diseases of Domestic Animals in Uganda. IV. *Trypanosoma uniforme*, sp. nov.; (2) Trypanosome Diseases of Domestic Animals in Uganda. V. *Trypanosoma nanum*. (Laveran): Colonel Sir D. Bruce, C.B., F.R.S., and others.—Some Enumerative Studies on Malarial Fever: Major R. Ross, C.B., F.R.S., and D. Thomson.—On Hæmoglobin Metabolism in Malarial Fever: G. C. E. Simpson.—A Case of Sleeping Sickness studied by precise Enumerative Methods. Further Observations: Major R. Ross, C.B., F.R.S., and D. Thomson.—Enumerative Studies on *Trypanosoma gambiense* and *Trypanosoma rhodiense* in Rats, Guinea-pigs, and Rabbits; Periodic Variations disclosed: Dr. H. B. Fantham and J. G. Thomson.—The Life History of *Trypanosoma gambiense* and *Trypanosoma rhodiense* as seen in Rats and Guinea-pigs: Dr. H. B. Fantham.—Experiments on the Treatment of Animals infected with Trypanosomes, by means of Atoxyl, Vaccines, Cold, X-rays, and Leucocytic Extract; Enumerative Methods employed: Major R. Ross, C.B., F.R.S., and J. G. Thomson.

THE CAVENDISH LABORATORY.

A History of the Cavendish Laboratory, 1871–1910. Pp. xi+342. (London: Longmans, Green and Co., 1910.) Price 7s. 6d. net.

THE occasion of this book is the fact that on December 22, 1909, Sir J. J. Thomson completed the twenty-fifth year of his tenure of the Cavendish professorship of experimental physics in the University of Cambridge. As the editors state in their preface, the suggestion was made by some of the professor's immediate colleagues that the event should be celebrated in some way which would commemorate a tenure so long and so full of achievement. Hence this history of the laboratory over which Thomson has presided for the greater part of its existence.

The general plan has been to divide the time covered by the history into periods, each of which has been treated by an author intimately acquainted with its events. The result is a marvellously interesting set of records. If the history had been written by one hand only, it would no doubt have been more continuous and concise, but it would have lost materially in charm and in value. As it is, the reader can well imagine himself in the company of a number of friends who have played important parts in a campaign, and who now relate in turn what they did and saw. And, of course, the campaign has been full of important events. Every student of physical science has been aware in a general sense of what he owes to the forward movements made in the Cavendish Laboratory. Yet in all probability even those who are best acquainted with the history of modern physics will find evidence in this volume of a greater debt than they had imagined. The list of papers published from the laboratory, a list to be found at the end of the book, is simply astonishing; it shows important additions made to every branch of physics. The names of the authors and workers in the laboratory include those of nearly all the best-known English physicists of to-day, and of many from abroad. In their contributions to the book itself the various writers give us something which is welcome and valuable. They bring about us the atmosphere of the place. We see the continual and unwearying struggle with the difficulties on that road which Maxwell and Thomson and their fellow-workers felt sure was the road to success. We realise their hopes and disappointments and successes as they try one line of attack after another; we share in the triumph of the final unearthing of the electron and in the rapid progress which followed on that unique discovery.

The story of the building of the laboratory is told by Fitzpatrick and Whetham, who also write of the commencement of instruction in practical physics at a time when there was hardly a precedent in such work to serve as guide. Schuster describes the period of Clerk Maxwell, whose commanding genius set a standard for his professorship and his laboratory. Two passages of Maxwell's writing are quoted repeatedly in the book; they have clearly been acknowledged as directions to his successors. The one is drawn from his inaugural address, and defines the aims and methods of experimental inquiry. The other is a flash of insight, the product of his brilliant work on electromagnetic theory. He saw that the phenomena of the electric discharge when better understood would "throw great light on the nature of electricity as well as on the nature of gases and of the medium pervading space." It is remarkable how fully this has been realised and how each one of the three questions which he mentions has since been illuminated by investigations in the direction which he points out. Best of all, a great part of this work has been done in the Cavendish Laboratory under the guidance of the man in whose honour this book has been written. Glazebrook writes of the fine work which was done under Lord Rayleigh, work characterised by Rayleigh's recognition that the accurate determination of electric standard had become a pressing matter. In 1884 Thomson succeeded Rayleigh. Thomson gives, in a chapter which is all too short, a survey of the twenty-five years that followed. It is naturally one of the most interesting chapters in the book. We read his own account of his work and of the gradual evolution of his principal discoveries, of his fellow-workers, of the system of teaching at the Cavendish, and of the classes that grew so rapidly under his rule.

No doubt Sir Joseph Thomson could hardly be trusted to write the full history of the doings in the laboratory during his own occupation of the Cavendish chair. That has been done by four men—Newall, Rutherford, C. T. R. Wilson, and Campbell, each closely concerned in the inquiries of the period which he has discussed. Newall describes the years between 1885 and 1894, when the interest centres round the general attack on the problem of the electric discharge. Rutherford writes of the three years of intense activity, 1895–8, when the position was stormed, the electron was captured, and Röntgen's X-rays supplied such a ready means of investigating phenomena in which the electron was concerned. C. T. R. Wilson describes the events of 1899–1902, including the elaboration and use of the condensation method which he himself did so much to perfect. Campbell shows the attempts to apply the new knowledge to "the fundamental problem of modern physics, the relation between electricity and matter." He gives also an interesting sketch of the curious and difficult situation into which the knowledge has led us. Finally, Wilberforce writes of the development of the teaching of physics with a keen sense, both of the difficulties of the art and of their compensating humour.

Taking the book as a whole it is, in the first place, a very charming testimony to the regard which the workers in the Cavendish entertain for Sir Joseph Thomson. He must be a happy man to note the generous and affectionate appreciation so widely evident in the book. In the second place, it will be of perpetual interest to students of physics as a record of the inner life of the Cavendish during a strenuous and prolific period. It is still more. It is practically the history of the development of laboratory teaching and organised research in England, so far as physical science is concerned. In many ways it is reassuring.

If we consider the work done, the number of first-class investigations, and the importance of the deductions made from them, we have no reason to be ashamed of our country's contribution to the general advance. We can be proud that so many students have proved their worth in the Cavendish and left it to fill important positions elsewhere, proud, too, that students from abroad have so freely acknowledged their debt to its spirit of enthusiasm and generous comradeship in research. It is true that the book leads us to consider the general question of physical research in England, and that we then find conditions which are not completely satisfactory. We have still to fight for the recognition of the value of such research, and we must in some way improve on the disjointed nature of the career of the research student. Too often his only reward is a teacher's position in which he finds difficulty in exercising the powers he has educated. But we cannot enter on the consideration of such questions now; we are only concerned with a book which fulfils admirably the purpose for which it was written.

A NEW BOOK ON REPTILES.

Reptiles of the World. Tortoises and Turtles, Crocodilians, Lizards, and Snakes of the Eastern and Western Hemispheres. By R. L. Ditmars. Pp. xix+373+87 plates. (London: Sir Isaac Pitman and Sons, Ltd., 1910.) Price 20*s.* net.

PRIMARILY intended as a general survey of the reptiles of the world treated in a popular manner, the handsome volume which has just appeared simultaneously in this country and in America, will prove of special value to all who keep these animals in captivity. The name of Mr. Ditmars is a guarantee of accuracy and originality in the treatment of a subject in which he excels over all others. The success with which he has managed for some years the largest collection of living reptiles in existence, viz., that in the New York Zoological Park, is well known. From early boyhood his enthusiasm for reptiles, especially snakes, has led him to study the habits of these reptiles, so repulsive to many, even among educated people, and his house has always been the headquarters of an extensive collection of snakes, large and small, innocuous and venomous.

The information he gives us is therefore thoroughly trustworthy, unlike what we find in so many so-called popular works, and we strongly recommend this book to amateurs who keep reptiles in captivity, as well as to those whose duty it is to look after them in public menageries.

The American species, of course, receive the lion's share in a treatise emanating from America, and in a publisher's note to this English edition the reader is asked to bear in mind that the species referred to by the author as musk turtles, mud turtles, pond turtles, box turtles, &c., are known in this country as tortoises, the term turtle being restricted to the marine, and sometimes a few of the larger river species. The reviewer would express the regret that the term Terrapin, used for some of the fresh- or brackish-water tortoises in America, has not been made to include these intermediate forms, which are neither true tortoises nor turtles. Further, the name sand lizard, applied to *Acanthodactylus boskianus* (p. 38) is misleading, as by sand lizard every English reader would understand our *Lacerta agilis,* which has always been known under that name. As is to be expected from an author who is not exactly a systematist—some may say all the better for the treatment of the subject in a popular style, the information as to the relationships and distribution of the animals dealt with, and the number of species in each genus, is not always quite up to date. Thus we notice that among the Chelonians the Carettochelydidæ are still included among the Pleurodirans, to which they were tentatively assigned before the skeleton was known, although it is now established that they belong to the Cryptodirans, in the neighbourhood of the Trionychidæ. The common snapping turtle is said to extend southward to Ecuador, whence it was first reported by the late Prof. Peters; but the reviewer was able to show, many years ago, that the snapping turtle of Ecuador is a distinct species, identical with the Central American *Chelydra rossignoni.* No allusion is made to the allied genus discovered a short time ago in New Guinea.

On the whole the author has adhered to the classification and nomenclature used in the British Museum catalogues (1885–96), but he has departed from the latter in the case of many North American types, which causes some confusion and a lack of harmony in the systematic treatment of the subject.

These are, however, very trivial defects. The great value of the work lies, as we have said, in the matter relating to the habits of the reptiles, both wild and in captivity, a subject on which the author is *facile princeps.*

The varied contrivances by which reptiles secure their food, produce and rear their young, harmonise with their surroundings, &c., are fully dealt with, and in a thoroughly original manner. The size to which the largest crocodiles and snakes grow is also discussed, and only trustworthy records are adduced. The largest crocodile measures 30 feet, so does the largest python, the anaconda rather more than 25, the *Boa constrictor* only 11; but it must be borne in mind that the name *Boa constrictor* is often applied to pythons in menageries and by colonists in Africa.

On the subject of snakes swallowing their young, it is important to have the opinion of an observer of such wide experience as Mr. Ditmars. "The story of the female snake swallowing her young in time of danger," he says, "is purely fallacious. It has originated from observations of cannibal species making a meal of young reptiles" (p. 203). Apropos of cannibal species, we wish to direct attention to the important experiments made on the king snake (*Coronella* or *Ophibolus getulus*) of North America, a harmless species, which is apparently immune to the venom of such deadly pit-vipers as the rattlesnake, the copperhead, the mocassin, and the South American Lachesis, whilst it usually dies within an hour if injected with the poison of the old-world cobras.

Mr. Ditmars's observations and experiments on chameleons and other lizards with changing hues have

convinced him that the colour-changes which these reptiles undergo with such rapidity are not, as often believed, in harmony with their surroundings, but are regulated chiefly by light, temperature, excitement, fright, or health. We here reproduce a partial list of these experiments on the common chameleon:—

Specimen A. Placed in the sunlight so that but one side of the lizard was exposed to the rays.

Specimen B. Placed in the sunlight at an angle to entirely suffuse the reptile with the rays.

Specimen C. Placed in a dark box; temperature, 73° F.

Specimen D. Placed in a dark box; temperature, 50° F.

After fifteen minutes, the following results were noted:—

Specimen A. Was a dark brown on the side that had been exposed to the sun; the shadowed side was a pale brown, mottled with green.

Specimen B. A uniform brown, deeper than the dark side of specimen A.

Specimen C. When the cover of the box was drawn the lizard emerged in a brilliant coat of green.

Specimen D. Crawled sluggishly from the cold quarters. Its colour was a uniform slaty-grey.

One curious effect of sunlight and shadow was noticed. A specimen had been basking under a coarse wire grating. Becoming frightened at the approach of the observer, it changed its position. On the dark brown body was what had been the shadow of the grating, brilliantly imprinted in pale yellow. Within half a minute this pattern had entirely faded.

The book is copiously illustrated with reproductions of photographs taken by the author from living specimens, and most of them are of high excellence. In some cases, however, the reduction is too great, such figures as those of the European lizards and the glass-snakes and slow-worm (plates xxxi*a* and xxxvii.) being, from this cause, practically useless. The snake figured on plate lxxvii as *Cerastes vipera*, and stated to measure about two and a half feet, is a hornless *Cerastes cornutus*. The author appears to be unaware of the existence of such hornless specimens, otherwise he would not have written (p. 328) that it is "impossible to mistake the horned viper," and that *C. vipera* is, but for the absence of horns, much like *C. cornutus*. A three-colour process figure of the rhinoceros viper, "the most beautifully coloured of all poisonous snakes," is given as a frontispiece.

G. A. B.

THE CALCULUS OF VARIATIONS.

Leçons sur le Calcul des Variations. By Prof. J. Hadamard. Tome premier. Pp. viii+520. (Paris: A. Hermann et Fils, 1910.) Price 18 francs.

NO one could be more competent than M. Hadamard to deal with the calculus of variations, and when this work is completed it will be a most valuable exposition of the present state of the subject. It is significant that in the first lines of his preface the author expresses the view that the calculus of variations is only a first chapter of the functional calculus (*calcul fonctionnel*) of Volterra, Pincherle, &c., and he gives, in fact, a short chapter on this new theory (pp. 281–312). But the analysis, in this volume, is mostly of a more familiar kind.

In fact, the first step in any actual case that naturally presents itself is still the classical one of Lagrange, by which we obtain a differential equation, or a set of differential equations. For simplicity, suppose the varied integral to be $\int f(x, y, y')dx$, then the differential equation is of the second order, and its solution is said to form a family of extremals. Supposing that the limiting values of x and the corresponding values of y to be given, then in the general case we may expect to find one extremal satisfying the terminal conditions. But it by no means follows that this curve really makes the given integral a maximum or minimum; an example due to Scheeffer is given on p. 45, which brings out the point very clearly. In this case the extremal found from the differential equation is $y=0$, and the corresponding value of the integral is 0; nevertheless, analytical curves can be drawn, as close as we please to $y=0$, which make the integral negative.

In any case, a solution obtained from an extremal is only a relative one; that is, the extremal gives a maximum or minimum value of the integral relatively to adjacent paths. And here it is important to define what we mean by *adjacent*, a fact first fully realised by Weierstrass, whose definition of adjacency of the *p*th order is given on p. 49. We may have, for instance, two curves each passing through the terminal points A, B, and as close together as we please, but one may be of continuous, the other of discontinuous curvature. Now, if we have a varied integral involving higher differential coefficients than y', we must exclude curves of discontinuous curvature, otherwise the problem becomes meaningless, and similarly in other cases.

After the limitations of the problem have thus been touched upon, book ii. deals with the first variation, and the conditions of the first order, including variable limits. Among other interesting points we have Weierstrass's transformation to homogeneous coordinates, a discussion of foci (points on the envelope of a family of extremals), and two very useful innovations due to M. Hadamard. If $\int f(x, y, y')dx$ is the varied integral, the *figurative* is defined to be the curve $f(x, y, y')=u$, in which u, y' are regarded as current coordinates, and x, y as constants. The *figuratrix* is defined as the polar reciprocal of the figurative with respect to $x^2+y^2=1$. By means of these curves the author is able to put various analytical conditions into a vivid geometrical shape. It may be added that book ii. contains the discussion of various classical problems, such as brachistochrones, least action, the Hamiltonian equations of dynamics, &c.

Book iii. introduces the second variation, and goes more deeply into the methods of Weierstrass, as well as those of Jacobi, Clebsch, Hilbert, Kneser, and others. We arrive ultimately at a statement, in various forms, of sufficient conditions for a minimum (pp. 389, 397), deduced mainly from the properties of a pencil of extremals, and a brief discussion of the necessary conditions, illustrated by examples (chapter iii.). The remaining chapters deal with variable limits, discontinuous solutions, Osgood's theorem in

connection with the strict minimum, and various other topics. Finally, there is a note on implicit functions.

Various interesting special theorems occur, by the way; as an instance, we have the theorem that if y vanishes for $x=a$ and $x=b$, the integral

$$\int_a^b \{(a-b)^2\left(\frac{dy}{dx}\right)^2 - \pi^2 y^2\} dx$$

is never negative.

It will be seen that this treatise is more for the advanced student than for the beginner; in fact, as the author expressly takes the theory of the differential and integral calculus for granted, the reader should be prepared with a good knowledge of analysis, including function-theory. In any case, the subject is intrinsically difficult, owing to the vagueness of the data when the problem is put in its general form; it is rather a matter of surprise that so much has been done, without unduly restricting the nature of the functions involved.

In conclusion, it should be stated that the treatise is based upon a course of lectures at the Collège de France, and that the *redaction* has been carried out by M. Fréchet, to whom M. Hadamard makes his acknowledgments.

G. B. M.

HYDROELECTRIC ENGINEERING.

Hydroelectric Developments and Engineering. A Practical and Theoretical Treatise on the Development, Design, Construction, Equipment, and Operation of Hydroelectric Transmission Plants. By F. Koester. Pp. xxv+454. (New York: D. van Nostrand Company; London: A. Constable and Co., Ltd., 1909.) Price 21s. net.

HYDROELECTRIC power plants do not call for the same attention in this country as in America and on the European continent. Yet what English engineer who has visited such installations has not a store of vivid recollections and happy experiences? The mountains and the forests, the streams and the waterfalls—for the generating stations of hydroelectric plants are usually away out among the beauties of nature—all bring back memories of pleasant tours and the like, whilst so far from destroying the attractiveness of their surroundings by harnessing nature's forces in this way, the author of the present work maintains that the scenery has at times been made more interesting, when proper attention has been paid to the architecture and situation of the buildings. This opinion is well upheld by many of the splendid photographs reproduced so well in this large volume.

The title of the book, however, is certainly ambitious, and, criticised from this point of view, we fear that the treatment on the whole is too general and descriptive, even to the point at times of being meagre, to be of great service to those directly connected with hydro-power plant installations. This will be further understood from the table of contents, which comprises chapters on dams, headrace, penstocks, power plant, mechanical equipment, electrical equipment, electrical transmission, substations, line protection, and a long list of developments, any one of which could occupy such a volume by itself. Hence it is almost inevitable that only a bird's-eye view could be given when all these subjects were brought within the compass of one book. It may be recalled that this popular mode of treatment appears to meet with more favour in America than in countries this side of the Atlantic. With this one reservation, however, we have nothing but praise for the general excellence of the book, the care devoted to its arrangement, and the high quality of its illustrations.

To show that the writer is well up-to-date, it is only necessary to refer to a few of the new features in hydroelectric developments which are dealt with in their respective chapters:—Airshafts and equalising chambers in connection with pressure tunnels; seamless welded, flangeless, telescoping penstocks to facilitate shipment and to eliminate expansion joints; siphon system, in contradistinction to the inverted siphon; impulse wheels with draft tubes and multiple, non-water-wasting nozzles; compound turbine on a single shaft, the discharge of one being the supply of the other; rapid and complete turbine tests by certain methods and autographic recording device; 30,000-volt generators and their efficient protective devices against lightning. Unique combination of single and three-phase high-tension transmission systems from three-phase generators; wagon-panel switchboard systems; segregation and decentralisation of switchboards; continuous water-flow grounders and horngaps with micrometric setting. Two-legged transmission towers and line-crossing protection.

At the end of each chapter is appended a bibliography of works and papers to which the student may turn for further information; this compilation is by no means the least valuable feature of the book.

Occasionally the author's treatment includes matter where his judgment seems to have been less sound. Thus in discussing electric generators, he states there are three types—the inductor, the revolving armature, and the revolving field. But surely there is no reason for treating all these at equal length?—indeed, little harm would have been done if the discussion of the first two types had been omitted completely in describing modern high-tension machines, unless, of course, the author intended to enter into the province of the designer in order to bring out certain advantages in the older types which have recently become prominent. Nor is sufficient attention paid to the development of high-speed water-turbine sets of large output. It would have been well to have supplied a table giving outputs and speeds of modern turbine sets for the various classes of turbines.

Here and there an error has been allowed to remain in the text, whilst at times important questions, such as the effect of capacity in transmission lines, have been omitted.

Following a very useful and well-written chapter on line protection (lightning arresters), the last section of the book is devoted to a detailed description of eight modern American and European hydroelectric developments, which serve well to show the immense advance made in water-power installations during recent years.

STANLEY P. SMITH.

THE ORIGIN OF COAL.

Die Entstehung der Steinkohle und der Kaustobiolithe überhaupt. By Prof. H. Potonié. Fünfte Auflage. Pp. xi+225. (Berlin: Gebrüder Borntraeger, 1910.) Price 7.80 marks.

THE study of the probable mode of formation of coal and kindred substances has for many years engaged the attention of Prof. Potonié, who, as palæobotanist in the University of Berlin, and also as a member of the Geological Survey of Prussia, has had exceptional opportunity for such study, both in the cabinet and in the field. At the York meeting of the British Association in 1906, he laid before the Botanical Section his views on the origin of coal, and the following year issued the fourth edition of his little work, "Die Entstehung der Steinkohle, u.s.w."—an octavo of only forty-seven pages, which was briefly noticed in NATURE (vol. lxxviii., p. 86). In the new edition, recently published, the work has been considerably enlarged, and the title so modified as to indicate that it deals with the origin of caustobioliths generally.

Under this term *caustobioliths* are included all those rocks or mineral substances which are, directly or indirectly, of organic origin, and are combustible, whilst such organic rocks as are incombustible, like chalk, are distinguished as acaustobioliths. In order to explain the origin of the fossil deposits, the author has wisely given much attention to the corresponding recent formations, or what may be reasonably regarded as such. Three great groups of caustobioliths are recognised. In the first place, there are the rocks called *sapropelites,* formed from organic slime, or sapropel, resulting from the partial decay of aquatic organisms and their products in stagnant water. When the sapropel, in a sub-fossil state, becomes gelatinous, it is distinguished as saprocoll, whilst the Tertiary forms are described as saprodil, and the older varieties as sapanthracon. It is a disadvantage that the work is rather heavily weighted with an unfamiliar terminology, but it must be conceded that most of the terms are expressive, and in many cases undoubtedly convenient.

Cannel coal, boghead mineral and many so-called bituminous shales are regarded as sapropelites, whilst petroleum is considered by Prof. Potonié to be a product of the natural distillation of deep-seated sapropel rocks, which have been exposed to heat and pressure during processes of mountain-building.

Another great group of caustobioliths is formed by the humus rocks, which result from the accumulation of the remains of land-plants and bog-plants. This important class contains not only many brown coals, but our ordinary coals and anthracites. Whilst sapropel rocks, generally present a dull surface, or a silky lustre, and when heated yield much gas, the humus rocks, or at any rate those of Palæozoic age, are usually lustrous and yield a smaller proportion of gas. Coal which shows an alternation of bright and dull layers is regarded as a mixed caustobiolith, derived partly from humus, partly from sapropel.

To Prof. Potonié common coal is a rock which in most cases has been formed where it is now found, mainly by the fossilisation of deposits of peat, often in far-stretching swamps. Considering the modern tendency, especially in France, to regard most coal as a substance of allochthonous formation, it is interesting to find a distinguished specialist upholding the view of "growth in place," which until recently has been so much favoured in this country.

Peaty deposits, though not formed of transported material, may exhibit stratification, and humus matter may be partially dissolved in water and precipitated in layers. The coal-forming peat was probably in a pulpy condition. In certain cases, the author suggests that the appearance of stratification is explicable as the result of pressure acting in a direction at right angles to that of the lamination. Prof. Potonié holds that the flora of the coal measures indicates a tropical climate, and cites instances of the extensive growth of peat in tropical swamps, as in the fens of Sumatra, described by Dr. S. H. Koorders.

Distinct from both the sapropelites and the humus rocks is a small group of caustobioliths called *liptobioliths,* of which amber and pyropissite are examples. The liptobioliths consist chiefly of resinous and waxy substances, which by their resistance to decomposition are left after the decay of the other parts of the original organism.

Throughout the work the author gives numerous references to original authorities, but unfortunately in most cases without sufficient detail, the reference being usually limited to the name of the author and date of publication, such as "vergl. Uthemann, 1892." The student seeking further information would be grateful for a little more definite guidance.

F. W. R.

THE VOICE AND SINGING.

(1) *The Brain and the Voice in Speech and Song.* By Prof. F. W. Mott, F.R.S. Pp. xi+112. (London and New York: Harper and Brothers, 1910.) Price 2*s.* 6*d.* net.

(2) *The Abuse of the Singing and Speaking Voice: Causes, Effects, and Treatment.* By Prof. E. J. Moure and A. Bowyer, Fils. Translated by Macleod Yearsley. Pp. xi+130. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1910.) Price 2*s.* 6*d.* net.

(3) *The Voice. An Introduction to Practical Phonology.* By Dr. W. A. Aikin. Pp. ix+159. (London: Longmans, Green and Co., 1910.) Price 7*s.* 6*d.* net.

THERE are now many manuals dealing with the voice and with the management of the voice and singing. These are unequal in value, more especially as regards the description of the anatomy and physiology of the organs of voice and speech, and not unfrequently the writer strongly advocates a view peculiarly his own, and on which he founds his method of training. It is therefore of importance to have a description of the organs concerned in voice

and speech from the hand of an experienced physiologist, who is at the same time sympathetic with music and with the arts of speaking and singing. This we have in Dr. Mott's admirable little book (1). Nothing could be better than the description he gives of the whole mechanism, and in language that any intelligent person can understand. In particular, and as one would expect from a distinguished neurologist, Dr. Mott shows the intimate relations of the organs of voice and speech to the brain centres of hearing and of motion, both as regards the delicate movements of the mechanism of voice and of articulation, and as regards posture and other bodily movements. Teachers of the art of voice production, as in singing or in the articulation of words and sentences in public speaking, know little of this side of their subject, and we feel sure that much of Dr. Mott's information will be to them a revelation. A study of his book will in some respects modify their mode of teaching.

(2) Messrs. Moure and Bowyer's book is of a different character. It deals with voice production in singing, but more especially with the serious mistakes that may be made by methods of teaching, or by the strain put on voices by singers themselves, that cannot fail to injure the vocal apparatus. We would recommend that a student should, in the first instance, carefully study Dr. Mott's book, and then take up that of the French authors. In the latter there is first an interesting historical sketch of the teaching of singing, from the time of the Romans onwards. The church was the first educator of singers, to meet the requirements of the plain chant. Trills, tremillos, and shakes by and by embroidered the tones, and it is curious that for many years falsetto voices were in great request. The invention of the madrigal in the sixteenth century enriched vocal music and made greater demands on performers. Thus much was done before a physiological basis was laid by Garcia, after the revelations made to him by his invention of the laryngoscope.

The description of the mechanism is not so thorough in the French book as that given by Dr. Mott, and it may give some superficial if not erroneous notions. The portion on the registers is well done, and more especially the description of the mixed or middle register. The chapter on "Vocal abuse" gives much valuable information. Both teachers and singers often forget that there should be a physiological harmony between different parts of the vocal apparatus. Pulmonary capacity, muscular power, the dimensions and delicacy of structure of the vocal cords, are all more or less related. Strong and sudden expiratory efforts made with the view of increasing the volume of the voice may injure delicate cords. A light tenor may make the mistake of trying to do what only a strong tenor can accomplish, or the tenor may even imagine he is a baritone. It is true that no laryngoscopic examination can enable a master to determine what his pupil is capable of doing, but a few trials, cautiously carried out with such solos for various voices as are given in detail on p. 104, would soon settle the question. Singers may also injure their voices by frequent displacement or change in the range of their voice. The same baritone in some circumstances may have to sing on successive days, or even on the same day, as a deep baritone or a high baritone of the Verdi type. Modern composers, and especially Wagner and his followers, have injured many voices by the demands they have made, as, for example, in *Tristan and Yseult*. They have been called "the executioners of the voice." Some singers never learn properly how to breathe, and by taking in too large a volume of air and expelling it with violence, by "bellowing," in fact, they may even produce emphysema of the lung. The chest voice is difficult to manage, and it may be much injured, by welding two registers, and thus destroying purity of tones. The scales showing the range of the registers on pp. 80–81 are very instructive.

There is an admirable chapter on some of the pathological effects of abuse. We find also an appendix showing the vocal ranges of varieties of voices, such as strong tenors, opera tenors, opera-comique tenors, baritones, high baritones, or Verdi baritones, basses, basso cantando, basso profondo, contralto, high soprano, mezzo-soprano, and dramatic soprano, and, to add to the interest of the list, the names of many of the distinguished artists of their day are given. The authors also point out, and illustrate by portraits, the relation that often exists between the physical appearance of the singer and the range and quality of the voice. There are some signs of haste in the translation; p. 15, line 4, should not "cause" be case? Second sentence on p. 21 not clear. It is difficult to understand the portion of the sentence at the top of p. 42. At middle of p. 42 insert "if" before he. As we have already indicated, the French Book is the complement to that of Dr. Mott, and both taken together leave little else to be written on the subject.

(3) This book is an admirable account of the mechanism of both speech and song. There is a full description of the physiological mechanism concerned in the formation of vowel tones and the sounds of consonants. The action of the vibrators (the vocal cords) and the management of the resonator (the cavities of the pharynx, mouth, nose, &c.), is illustrated by exercises which a reader can readily follow, and the rules to be attended to in the management of the breath are given with physiological explanations. Two notable features of the book are a pronunciation chart showing methods for the practice of English pronunciation, and figures termed by the author "Song diagrams," showing the capacity of the various kinds of voices, from deep bass to high soprano. Composers would do well to study the figures on pp. 138, 139, and 140, where they would see at once the exorbitant demands on the voices of great operatic singers made by certain composers, notably by Wagner and even by Beethoven. The effect of the prolongation of very high tones may be brilliant and striking, but their production must cause, in many cases, serious tear and wear to a fine voice. As a truly scientific exposition, dealing with a subject that has an important practical aspect, Dr. Aiken's book is to be strongly recommended.

John G. McKendrick.

OUR BOOK SHELF.

Die Wissenschaftlichen Grundlagen der analytischen Chemie. By W. Ostwald. Fünfte Auflage. Pp. xii+233. (Leipzig: W. Engelmann, 1910.) Price 8 marks.

THE appearance of a fifth edition of this well-known book affords gratifying evidence of the widespread recognition that the study of analytical processes from the theoretical point of view is a necessary adjunct to the practical work of the laboratory. At the same time, the continued demand for a book of this character is a striking testimony to the general utility of the ionic hypothesis in the consideration of the problems of analytical chemistry. In spite of the many attacks, persistent and vigorous, which have been made upon the theory of Arrhenius, it has to be admitted that its position as a working hypothesis is stronger to-day than it was at the time of issue of the first edition of this volume.

The changes to be found in the new edition are comparatively few. The principal novelty consists in a slightly modified treatment of the theoretical portion as a result of the introduction of the view that the stochiometric laws are, in a certain sense, a consequence of the methods which are employed for the preparation and identification of compounds. In this connection the conception of *phase* is introduced, and since a phase may be either a pure substance or a solution, the problem of differentiating between these two classes is obviously one which falls within the sphere of analytical work.

Little need be said of the section dealing with the applications of the ionic theory to specific chemical reactions. In the explanation of the action of the indicators used in acidimetry, it is now admitted that the indicator ion has probably a different structure from that of the non-ionised indicator molecule. Few changes have, however, been found necessary as a result of recent work, and the characters are retained which have earned for the book the right to be counted amongst the classics of the literature of analytical chemistry. H. M. D.

The "Wellcome" Photographic Exposure Record and Diary, 1911. Pp. 280. (London: Burroughs, Wellcome and Co., n.d.) Price 1s.

THIS little pocket-book is a veritable *vade mecum* of photography in tabloid form, and while the present writer never wishes to be without his copy when out with his camera, he is sure other workers, when they become acquainted with the contents of these pocket-books, will express the same sentiments.

There is no necessity to recapitulate in detail the literary portions of this book, but suffice it to say that they are of a very interesting and useful character, and besides dealing with the technical difficulties of exposure, development, &c., and colour photography, they include directions concerning negative-making, tank or stand developing, printing, toning, intensifying, and so on. In addition to the portion devoted to the recording of negatives exposed, there is ample room for memoranda to replace the use of an ordinary notebook. An important feature is the simple and effective exposure calculator attached to the inside of the cover, the correct exposure being read off under all conditions of light and subject by a turn of the scale. For this issue, this calculator is rendered even more simple for those who always employ plates or films of one speed. By the insertion of a special disc, which may be obtained gratis from the publishers, the exposure can be read off at a glance for any stop. This special disc will be particularly useful to those who expose yards of film in their Kodaks or other hand cameras.

It should be remembered that three editions of this "Record and Diary" are published, with corresponding data for the northern hemisphere and tropics, the southern hemisphere and tropics, and the United States of America. Handy in form, and bound in a neat green cover, it will find favour with most photographers.

Reason and Belief. By Sir Oliver Lodge. Pp. xiv+212. (London: Methuen and Co., Ltd., 1910.) Price 3s. 6d. net.

THIS is a contribution to the literature of reconciliation. The science and religion of the nineteenth century were hopelessly at variance, chiefly in consequence of the latter's claim to pronounce in matters of cosmology (*e.g.* Mr. Gladstone's "Impregnable Rock of Holy Scripture"). But the conditions are now different. Religion is being regarded as "an attitude of the soul to all that it knows of cosmic law"—in Myers's phrase—rather than as a matter of dogma; and science, also, is learning humility. Crude materialism is seen to be no complete solution of the riddle of the universe, for we do not know what "matter" is. Moreover, psychology is bringing to light certain phenomena which orthodox scientific theories do not seem to cover. The time, therefore, is ripe for a *rapprochement*; and among leaders of thought on the scientific side of the reconciliation movement, Sir Oliver Lodge is by far the most eminent and the most influential.

Man is a being who is temporarily clothed in matter, for purposes of education. He has lived before birth, and will live after "death," in modes only dimly conjecturable at present. If so, what difficulty is there in supposing that an exceptionally great and loving spirit, seeing the race's need, may voluntarily take a body of flesh, in order to teach his similarly incarnated brother spirits? This shows the way to a reconciliation of reason and belief on a cardinal doctrine of Christianity.

The volume is enriched with apt quotations from many sources—Wordsworth, Browning, Tennyson, Swinburne, Myers, Francis Thompson, &c. Its style is popular and clear, but the thought throughout is deep and suggestive. The latter part has an illuminating chapter on the scope of science, and also deals with the teaching of the Old Testament in the light of evolution, and with anticipated criticism. J. A. H.

Altitude Tables, computed for Intervals of Four Minutes between the Parallels of Latitude 0° and 30° and Parallels of Declination 0° and 24°, designed for the Determination of the Position-line at all Hour Angles without Logarithmic Computation. By F. Ball. Second edition. Pp. ix+245. (London: J. D. Potter, 1910.) Price 15s. net.

THE appearance of a second and improved edition of these tables is welcome on several grounds, but mainly as an indication of increasing accuracy in nautical calculations. We hope, too, that the demand for such tables may be regarded as a proof of the growing popularity of the method of determining the position of a ship at sea proposed by Captain Marcq St. Hilaire, of the French Navy. This method, though theoretically superior to that of finding the Sumner lines by the ordinary process, has not been generally adopted, on account of the slight increase in the computations required. Seeing that in the St. Hilaire method, the observations may be made at any time with equally good and consistent results, whereas in the ordinary method, observations taken near the meridian may have to be repeated nearer the prime vertical, the objections that have been alleged against the newer method on account of the length of the

observations ought not to be allowed to prevail. The sailor expects to find tables at hand that shall curtail the arithmetical processes to a minimum, and these tables, the main feature of which is to give readily and accurately, at sight, the altitude of the sun or of stars within the ecliptic limits, at least in the more frequented latitudes, will remove one of the objections that have been urged.

Other tables suggested by experience have been added in this edition in order to increase its utility and avoid the necessity of further reference. With these tables and a nautical almanac, it is said that the navigator can complete his task. We would, however, allow him a book of logarithms, for the tables given here are too restricted to serve any useful purpose. One might need to check the accuracy of some of the quantities supplied, though we have no reason to doubt the general accuracy of the tables, for which Dr. Crommelin and some of the staff of the Royal Observatory are responsible.

Metallography Applied to Siderurgic Products. By Humbert Savoia. Translated by R. G. Corbet. Pp. xii+180. (London: E. and F. N. Spon, Ltd., 1910.) Price 4*s*. 6*d*. net.

THE Italian original of this little book was obviously intended to bring the more essential parts of the metallography of iron and steel within the reach of Italian metallurgists, but what motive there can be to justify the translation into English of such an elementary compilation it is not easy to understand, particularly as satisfactory original works in our own language are now available. In the book as it stands the feats of the author are largely disguised by the achievements of the translator, who appears to have invented an entirely new nomenclature not only for purely metallographic terms but for well-known and widely-used technical words. That the translator disclaims technical knowledge of the subject-matter of the book and begs for indulgence in regard to technical terms cannot, unfortunately, alter the fact that much of the book would be rendered unintelligible to the non-expert reader for whom it appears to be intended by such glaring translator's errors as the use of "tempered" for "hardened," mechanical "elaboration" for mechanical "working," "resolving" for "dissolving," "composite" for "compound" in its chemical sense, "soldered" for "welded," "strain of extension" for "tensile strength," and many others; perhaps the most amusing example of the translator's misinterpretation of the Italian words occurs in the description of the Le Chatelier thermo couple as consisting of "platinum and radiated platinum."

Apart from these serious defects, the subject-matter of the book is not free from errors; thus the text of p. 69 definitely suggests that "pearlite" is formed from molten steel, and indeed throughout the text the difference between the eutectoid pearlite and a true eutectic is not indicated. The most satisfactory portions of the book are those dealing with malleable cast-iron, where the author is evidently on his own ground, but, taken as a whole, the book cannot be recommended to students of metallography.

W. R.

Researches upon the Atomic Weights of Cadmium, Manganese, Bromine, Lead, Arsenic, Iodine, Silver, Chromium, and Phosphorus. By G. P. Baxter, and others. Pp. vii+185. (Washington: Carnegie Institution, 1910.)

THIS memoir, which is published through the munificence of the Carnegie Institution of Washington, is one of the many series of similar researches which we owe to the Harvard School of Chemistry. It comprises eleven separate investigations on the atomic weights of the elements enumerated in the title, the results of which have been published in American and German periodicals at intervals during the past six years.

In the form in which they are now presented a few minor alterations have been made, necessitated by a more precise knowledge of certain of the fundamental values upon which the determinations are based. Certain of the original papers have had their subject-matter rearranged. The eventual results have, however, already been incorporated in the last annual report of the International Committee on Atomic Weights, and are therefore readily accessible to all workers.

Practical Measurements. By A. W. Siddons and A. Vassall. Pp. xiv+60. (Cambridge: University Press, 1910.) Price 1*s*. 6*d*.

THIS book is a development of the course of physical measurements founded by Mr. Ashford at Harrow in 1896. Recently the earlier portions have been worked under the mathematical staff. The course follows closely the syllabus of the joint committee of the Mathematical and Science Masters' Associations. It is important that teachers should read the authors' observations on p. vii., as there is a danger that the work may lead boys to suppose that "science" and "measurement" are synonymous. The course is open to the serious objection that it provides a long series of measurements which are purposeless from the boy's point of view. Thanks to the experience and shrewd observation of the authors, the book may serve as a trustworthy aid to mathematical teachers who are undertaking, for the first time, the control of classes engaged in laboratory work. Such teachers will find their routine work improved as well as lightened by its use. To sum up, the book provides a well-planned drill of a not too interesting kind, and makes it possible to insist on the work being properly done by the boy who desires to have a too easy time.

The Year-Book of the Scientific and Learned Societies of Great Britain and Ireland: A Record of the Work Done in Science, Literature, and Art During the Session 1909–1910 by Numerous Societies and Government Institutions. Compiled from Official Sources. Pp. iii+370. (London: Charles Griffin and Co., Ltd., 1910.) Price 7*s*. 6*d*.

THIS is the twenty-seventh annual issue of a widely known and very useful work of reference to which attention has often been directed in these columns. We have noticed several additions to the list of societies and associations, the work of which is described. It seems strange, however, to find in a volume issued at the end of 1910 particulars of the Winnipeg meeting of the British Association in 1909 and no references to the meetings of the association at Sheffield this year.

Cambridge. Described by N. Barwell. Pp. 64. *Norwich and the Broads.* Described by W. Jerrold. Pp. 56. *The Heart of Wessex.* Described by S. Heath. Pp. 64. All pictured by E. W. Haslehust. (London: Blackie and Son, Ltd., 1910.) Price 2*s*. net each.

THESE latest additions to the series known as "Beautiful England" are likely to be popular guide-books to the districts with which they are severally concerned. Mr. Haslehust has been successful in giving in his pictures delightful impressions of the different counties, and visitors will be glad to have the volumes to remind them of the beauties of the holiday resorts they have frequented. The descriptions are gossipy and entertaining.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Morphological Method and the Ancestry of Vertebrates.

THERE has just reached me the Proceedings of the Linnean Society for October, containing the report of an interesting discussion upon the "Origin of Vertebrates" which took place at meetings of the society in January and February of this year. Apart altogether from statements as to matters of fact which seem to be open to challenge, this discussion appears to me to raise points in regard to the methods employed by the morphologist which are of practical importance to those interested in the science of morphology.

The remarks made by Dr. Gaskell and his supporters make it apparent that there exist wide differences between what they accept as the correct principles of morphological research and those which are accepted by other working morphologists. Personally, I have been devoting myself for some time past to researches dealing with the evolution of vertebrate structure, and my impression is that there can be no wider gulf than that existing between the working principles apparently adopted by Dr. Gaskell and those adopted by myself and many other morphologists. If the principles of morphological speculation employed by Dr. Gaskell are sound, it seems to follow that those held by the majority of morphologists are absurd, and that the work based upon them represents in great part wasted labour. I will endeavour to throw into relief some of these radical differences of opinion as to general principles which appear to separate many of us from Dr. Gaskell and his friends. I feel all the more impelled to do so when I read the words of a distinguished physiologist who took part in the discussion:—"I am convinced that the principles on which he [Dr. Gaskell] has proceeded are the only ones which will lead to a solution of the problem." I fully realise that there are physiologists who would feel it rash to express themselves so decidedly as to what are, or what are not, the correct principles upon which to work in a science other than their own. Nevertheless, it seems quite clear that Dr. Gaskell's views—though they may not appeal to many who are specialists in vertebrate morphology—do produce a strong impression on many workers in other departments of biological science.

What are the principles which must be followed in speculations regarding phylogeny if these speculations are to be trustworthy? It is clear, in the first place, that whenever possible such speculations should rest upon a tripod basis of comparative anatomy, embryology, and palæontology. It is clear, further, that in fashioning each foot of the tripod certain definite rules must be adhered to if the foot is to be sound and sufficient to support the weight which is to rest upon it. For example, in making use of the data of palæontology, we have to bear in mind, firstly, that the geological record, and still more our knowledge of that record, is and must always be of the most fragmentary character, and, secondly, that in all phylogenetic speculation it is unsafe to trust to data dealing only with one single set of organs, whether these be the skeletal organs—alone, as a rule, available to the palæontologist—or any other system of organs. In the case of comparative anatomy and embryology we must bear in mind that a feature has a *prima facie* greater importance or not according as to whether or not it occurs in a more or less "primitive" group. Then, again, in both comparative anatomy and embryology it is necessary to devote great care and attention to the sifting out of features which are mere adaptations to modern environmental conditions from those which are ancestral. Finally, it has to be borne in mind that in comparative anatomy we are beset by the same kind of difficulty as that of the protozoologist when he tries to piece together isolated observations on dead material into a connected life-history, while in embryology, on the other hand, the facts, such as they are, appear to be presented to us all ready arranged in their phylogenetic sequence. These general principles apply to all phylogenetic speculations, and morphologists are probably all in agreement regarding them.

Now as regards the phylogeny of the Vertebrata. When a student under Sedgwick at Cambridge I began to realise that perhaps the most clamant need in vertebrate morphology was for a broadening of its observational basis, particularly in regard to the embryology of the more primitive forms of vertebrates. There seemed general agreement that the elasmobranchs, crossopterygians, lung-fishes, and urodele amphibians were all "primitive" groups as compared, *e.g.*, with teleostean fishes, reptiles, birds, and mammals. It seemed clearly indicated that if we were to have the general ideas of vertebrate embryology upon a trustworthy basis it was essential that the development of the crossopterygian ganoids and lung-fishes should be worked out to a similar degree of detail to what had been accomplished in the case of the other groups. My own research work during the last fourteen years has been directed according to this ideal, and has been devoted to the study of the morphology of the four relatively primitive groups mentioned above, together with, of course, the cyclostomes. As I fail to see how there can be any other scientific method of approaching the problem of vertebrate phylogeny than that which starts from a comprehensive study of such surviving forms as are admitted to be the more primitive, I may be excused for venturing to offer these remarks regarding the discussion at the Linnean Society.

One of the points raised in the discussion is the very important one, upon which I have elsewhere expressed opinions—the relations of physiology and morphology. No one has, I dare say, a greater horror than I have of that type of zoologist sometimes referred to as the "mere" morphologist—the zoologist who fails to keep before him at every moment of his work that he is dealing with living functional organisms, who fails to realise that at every stage of its evolution an organ must, in the first place, be able to function. I have at various times criticised evolutionary speculations, *e.g.* on the evolution of renal organs, or of the vertebrate limbs, or on the inadequacy of natural selection, because they seemed to ignore important physiological or functional considerations. While taking the greatest care to keep physiological considerations before us, we must, however, not forget that the *facts* upon which the evolution theory is based are morphological facts. We know nothing as yet of "recapitulation" in physiology; we have in the rocks no record of physiological change; even the science of comparative physiology is still in its infancy. The whole record of evolution is and must necessarily be mainly, if not entirely, a morphological record.

Another principle which is of much importance in morphological work is this: the greatest care must be taken to make the observational basis of speculation as broad as possible. The fewer the organs or the organisms that are made use of the less trustworthy are the conclusions drawn. *E.g.* a detailed study of the radiate eye of an insect and of a stalk-eyed crustacean brings to light the most striking resemblances, so much so that if we only knew one genus of each group and only the eye structure in that genus we should be inclined to suppose the two genera to be closely allied. I need not say that a study of the general morphology of the Antennata on the one hand and the Crustacea on the other indicates that they have been evolved separately from a simple ancestral form which existed probably long before the radiate eye had become evolved. The same kind of principle holds in regard to organisms. The detailed study of the structure of two animals may bring to light the most astounding resemblances in details of structure, and it may, nevertheless, be the height of rashness to attribute the resemblance to genetic affinity unless there exists collateral evidence which supports the view. Yet Dr. Gaskell says, "my object throughout has been by the study of Ammocœtes to find out a clue to the past history of these extraordinary early forms of fish." Is the ordinary zoologist like myself completely in error when he thinks that for "Ammocœtes" there should have been written the words "cyclostomes, crossopterygians, elasmobranchs, lung-fishes, and amphibians" in formulating

Dr. Gaskell's programme of work at this immense problem of the ancestry of vertebrates?

Personally, were I concentrating in this way on the study of Ammocœtes, I should be constantly oppressed by an uneasy feeling of absolute uncertainty as to the extent to which the cyclostomes are primitive in their structure and to which specialised for their extraordinary habits, unique amongst vertebrates. Certainly we should expect *a priori* that vertebrates that took to such a mode of life would tend to become extremely specialised. We do not even know for certain whether they are derived from jaw-possessing ancestors, though we cannot help suspecting that a vertebrate taking to the cyclostome mode of life would tend to lose its hinged jaw and become, therefore, cyclostomatous.

Another cherished principle of morphological research receives a rude jar in Dr. Gaskell's sentence, "to me and to all my friends who are accustomed to deal with the vertebrate nervous system the explanation I have given is so self-evident and natural that it is impossible to look at the matter in any other way." Are myself and other teachers of morphology talking nonsense when we urge upon those commencing research work that the frame of mind which they must endeavour to avoid at all cost, if their work is to be of value, is that in which they come to regard their working hypothesis as "so self-evident and natural that it is impossible to look at the matter in any other way"?

An important principle is that enunciated by Dr. Gaskell when he says that "each higher group of animals has arisen in succession from the highest race developed up to that time, by highest meaning the group possessing the best developed central nervous system." Apart from the trivial point that many would differ from Dr. Gaskell in their estimate of the trustworthiness of the palæontological statements by which this principle is illustrated, the principle itself seems to many a somewhat doubtful one. I take it by "high development" we mean, roughly, "complexity of organisation." Now organisation is upon the whole adaptive to functional activity. A highly organised animal is, as a rule, one the details of the structure of which are highly specialised in relation to environmental conditions. Such adaptive specialisation of the various organs renders their possessor peculiarly liable to suffer from changes in environmental conditions. It seems probable that changes of environmental conditions form one of the chief factors in compelling evolutionary change. It is at such periods that natural selection is most accentuated: the adaptable survive, the unadaptable are exterminated. It appears quite credible that when important geological or other environmental changes come about it is those forms the organisation of which shows the most complete linking up to the preceding set of conditions which are exterminated, in other words, that it is *not* the highest existing forms which proceed to evolve into a state of adaptation to the new set of conditions.

Apart from general principles, there are many important statements as to fact which seem to me to call for comment. Amongst these, for example, I read that "the evidence of the rocks points to the Silurian age as the time when the vertebrate first arose." To me it is simply incomprehensible how any biologist can really believe that the scales and teeth, comparable in complexity with those of existing fishes, occurring in Silurian formations, can be taken as having any bearing whatever upon the question of the first appearance of vertebrates. There are indeed, I think, many who feel compelled to admit that the period of evolutionary time intervening between the first appearance of the simplest chordates and the appearance of these Silurian fishes may well have been as great or greater than that which has intervened between the Silurian times and the present day.

Dr. Gaskell refers to zoologists "accepting as a commonplace the manufacture of a new organ for breathing air instead of water in the transition from the fish to the amphibian." He also says that the evidence seems to him stronger that the vertebrate alimentary canal has been formed from a pre-existing respiratory chamber "than that an alimentary canal should have taken on a respiratory function in its anterior end." I would only remark that anyone who studies the evolution of the adult vertebrate from the embryo can see for himself, as a matter of fact, that the anterior end of the alimentary canal does develop a set of gill clefts, *i.e.* a mechanism which in fishes is respiratory. Further, the only morphologist who has had the opportunity of studying the development of the lung in the lowest lung-bearing vertebrates asserts that the homology of the lung or swim-bladder of fishes with the lung of the higher vertebrates appears to him to be beyond question, and he takes the view that the lung, instead of developing "in the transition from fish to amphibian," was in all probability already present in the ancient common ancestral form from which teleostomatous fish, lung-fish, and all the higher vertebrates have been derived.

Dr. Gaskell refers to the old idea that the infundibulum of the vertebrate brain represents the œsophagus of the invertebrate, and that the suprainfundibular part of the brain represents the supraœsophageal ganglia. Such an idea would only be of value as a scientific hypothesis if based upon the facts of the earlier stages of brain development in the more primitive groups of vertebrates. I have personally studied the development of the brain in elasmobranchs, crossopterygians (Polypterus), actinopterygian ganoids (Amia, Lepidosteus), lung-fishes (Ceratodus, Lepidosiren, Protopterus), and urodele amphibians. The phenomena seen in these forms do suggest certain conclusions as to the general morphology of the vertebrate brain, as that the hemispheres are primitively paired or that the primary subdivision of the brain is into two rather than into three parts ("vesicles"). They do not suggest, however, any such view as that referred to. On the contrary, they appear to me to indicate that the part of the central nervous system which in the annelid or arthropod has become the supraœsophageal ganglia has in the vertebrates completely disappeared.

Dr. Gaskell refers to those views which "turn the animal topsy turvy, making the back of the invertebrate correspond to the ventral surface of the vertebrate." As a matter of fact, the only two stages of vertebrate ancestry which may be regarded as established with a fair degree of probability are:—(1) a protozoan stage recapitulated in the unicellular zygote, and (2) a cœlenterate stage repeated in the diploblastic stage of Amphioxus and in the corresponding stages of lampreys, elasmobranchs, crossopterygians, lung-fishes, and amphibians. We know, of course, nothing of the details of structure of the diploblastic ancestor, but it has been suggested by Sedgwick and others that these ancestral forms passed through a stage resembling in its general features the existing actinozoan. This idea, which in my opinion is still a perfectly reasonable working hypothesis, affords an adequate explanation of developmental phenomena otherwise extraordinary and ununderstandable, such as the occasional occurrence of a mid-dorsal slit dividing the central nervous rudiment and notochord into lateral halves. It would clearly be unfair to state that such a view is "doomed to failure" because it makes the back of an invertebrate correspond to the ventral surface of a vertebrate. The view does not assume the reversal of the body. It merely refers back vertebrates and cœlomate invertebrates to a common ancestor in which there was no ventral or dorsal surface—a form in which there was a certain amount of concentration of the nervous system in the region round the primitive mouth or protostoma—and suggests that in certain of the descendents of this ancestral form the normal position of the body is with the neural surface beneath or ventral (annelids, arthropods, molluscs), while in others (vertebrates) it is such that the neural surface is uppermost or dorsal.

A strong point about this view is that it suggests a possible origin of the segmented character of the mesoderm of the vertebrates. It is generally agreed that the mesoderm is of enterocœlic nature, and it was emphasised long ago by Sedgwick that just such a segmentation of enterocœlic pouches is already present within the phylum Cœlenterata in the Actinozoa.

Prof. Starling in the discussion said:—"To an onlooker like myself the striking resemblance between the earliest fishes and the Arthropoda . . . is striking evidence in favour of Gaskell's theory." Morphologists, unfortunately, have as yet no knowledge of the earliest fishes. They are acquainted only with certain dermal skeletal structures and a few impressions which give a vague

notion of the general form of certain Silurian "fish-like" forms. Assuming, however, that it is the case that to the onlooker there is a striking resemblance between the earliest fishes and the Arthropoda, it is necessary to point out that striking resemblance in superficial characters provides a type of pitfall which the morphologist has at an early stage in his education to school himself to avoid. He comes across cases of amazing resemblance, *e.g.* in pairs of "mimetic" butterflies, between a marsupial and a placental mammal, between the organ of vision of one of the higher insects and that of one of the higher Crustacea, between the skeleton of a flagellate and that of a radiolarian, and he learns to recognise that superficial resemblance may, and frequently does, provide a cloak for fundamental unlikeness. It is, in fact, one of the main parts of his business as a morphologist to find out whether in each particular case the striking resemblance so apparent to the onlooker is an expression of resemblance in fundamental points of structure or whether, on the other hand, it is merely superficial.

I think I have now said enough to make apparent how greatly some of us who devote ourselves to the problem of vertebrate phylogeny differ from Dr. Gaskell and those with him in what we regard as the necessary principles in accord with which morphological work must be done. As regards Dr. Gaskell's main thesis, that vertebrates are descended from arthropods, we take the position that what is known of the morphology of vertebrates in general, and of arthropods in general, does not justify the regarding of that view as a reasonable working hypothesis. Were Dr. Gaskell to increase by several fold his mass of detailed anatomical resemblances between an undoubted arthropod and an undoubted vertebrate, we should feel ourselves confronted, not by a demonstration of near genetic affinity, but rather by a fascinating puzzle in the way of convergent evolution. It would take up too much space, and perhaps serve little purpose, to indicate the general considerations, the cumulative effect of which is to force zoologists into the position I have indicated. I may, however, just indicate one feature, the character of the skeleton, which, as it happens, is a highly characteristic feature alike in the arthropods and in the vertebrates. In the Arthropoda we find one of the finest evolutionary inventions existing in the animal kingdom—a supporting skeleton formed out of waste products of metabolism, and so spread over the surface of their body as to form an armour effectively protecting the delicate living tissues of the body from the most varied kinds of dangers. That a group of free-living arthropods should have given up this magnificent protective device is not, of course, incredible, but before being accepted as probable it would have to be supported by an overwhelming mass of evidence.

What evidence do we, in fact, find as to the nature of the skeleton of the primitive vertebrate? We find in the vertebrate that the skeleton in the earliest stages of its development consists of a cellular rod cut off from the dorsal wall of the gut and running longitudinally along the median plane of the body. This rod, the notochord, which still persists as the main axial skeleton in the adults of some of the lowest vertebrates, occurs during embryonic development, not merely in a few vertebrate forms, but in every lower vertebrate the embryology of which has so far been investigated. There is not a single exception. Could evidence be more overwhelming that the ancestral vertebrate was a creature with a skeleton in the form, not of a hypertrophied cuticle, but of a cellular notochordal rod formed from the wall of the gut? Dr. Starling would object that "no palæontological evidence seems to be brought forward in favour of this hypothesis." The answer is a perfectly simple one. Palæontology can from the nature of the case offer us hardly any evidence whatever in regard to structures composed of soft, perishable organic material. By far the greater part of the tissues and organs with which the morphologist deals are composed of such soft, perishable materials, and all these structures, upon the *cumulative* evidence of which (taken in conjunction with the much smaller amount of evidence obtained from the skeleton) he bases his conclusions, are almost entirely absent from the geological record. I might go farther and point out that a highly developed, highly rigid skeleton is in itself a product of long-continued evolutionary change. Each animal possessing such a skeleton is the descendent of a long line of soft protoplasmic forms in which the skeleton had not yet become evolved, and these ancestral forms have, so far as palæontology is concerned, vanished for ever from our ken. It is upon the study of the comparative anatomy and embryology of existing forms alone that we have to depend when we endeavour to form a picture of what these ancestral forms were like.

The foregoing paragraphs are not meant as a criticism of Dr. Gaskell's hypothesis. They are merely meant to direct attention to an extraordinary want of agreement as to methods or principles of morphological research. It is clear that work in any department of science must be done according to some definite set of principles if it is to be of any appreciable value. In morphology, as in other sciences, there are certain generally accepted principles. It seems to me not unreasonable to ask that workers who take up morphological research should either accept these general principles and be guided by them, or, if they find themselves driven to formulate a new and better set of principles, that they should at least state these clearly and give their fellow-workers the opportunity of judging in what respects they are better and more trustworthy than those in ordinary use. Unless this is done there is apt to be caused an irritating waste of time and energy. There is, further, the danger that important work may be rejected without adequate examination, not because of its inferior quality, but simply because of the difficulty in the way of discovering common factors between it and work on the more ordinary and orthodox lines.

Mendelian Expectations.

MR. LEWIS BONHOTE has confirmed Mr. R. Staples Browne's statement that the web-foot in pigeons is a simple Mendelian recessive, but he finds that when webbed birds from two different strains are crossed an irregular result is obtained, viz. four normal and one webbed. Moreover, mating the first crosses yielded results in almost every case contrary to Mendelian expectations, normals throwing webs and webs throwing normals (NATURE, December 1, p. 160). Similar results have been obtained with West Highland terriers, in which white is apparently recessive to yellow. The offspring of pure-bred white terriers belonging to the same strain are white, but the offspring of pure-bred white terriers from different strains are sometimes yellow. Further, a hybrid (yellow) which produced more than 50 per cent. of white pups to a white dog of her own (Inverness) strain produced only yellow pups to a white dog of a different (Poltalloch) strain.

The explanation of these "irregular" results seems to be that the normal toes, presumably latent in webbed pigeons, and the yellow coat, presumably latent in white terriers, are restored when two strains having a somewhat different history are interbred, *i.e.* mingling the blood of two strains induces reversion. Because "points" are lost when two strains are crossed, many breeders are extremely reluctant to introduce new blood even when their stock is obviously deteriorating from in-and-in breeding. Recently a very successful breeder assured the writer that nothing in the world would induce him to use the blood of another strain to improve his white Highland terriers, and it is notorious that breeders of sheep and cattle have once and again allowed their flocks and herds to lapse owing to their reluctance to infuse fresh blood from other strains. Further, Von Oettingen has pointed out that, in the case of the English racehorse, the more remotely related the parents the less chance there is of the offspring winning races.

If crossing two strains is liable to lead to reversion, we can understand why in some hands breeding is such a lottery, why, *e.g.*, the offspring of two record racers or trotters are sometimes complete failures. The English thoroughbred breed is made up of several distinct types, each of which is now and again represented by a Derby winner. When two fleet but not too closely related members of the same type are mated, the result may prove highly satisfactory, but when the sire belongs to one type and the dam to another, and when, in addition,

the parents are so remotely related that they are separated by seven or more "free generations," the chances are (unless one of the parents is highly prepotent) that, notwithstanding the great merits of the immediate ancestors and the expectations of Mendelians, the offspring will revert to mediocrity. Hence it is not enough that breeders should "mate the best with the best, avoiding close affinities"; they must avoid crossing distinct strains even when the members of one strain closely resemble those of another. This implies that, in addition to knowing the pedigree of their stock, breeders should know as much as possible of the wild races from which modern varieties and strains were originally derived.

Arctic Plants from the Valley Gravels of the River Lea.

I HAVE recently found a plant-bearing bed in the Low Level River-Drift of the Lea valley at Ponder's End. It is exposed in an excavation worked by the Great Eastern Railway Company, and I am indebted to Mr. Horace Wilmer, engineer to the company, for permission to carry on my investigations.

The plant-bearing bed is found at a depth of 14 to 18 feet below the surface. It is embedded in stratified gravel and sand, which presents much evidence of tumultuous accumulation. In immediate association with it are found tusks, teeth, and bones of the *Elephas primigenius*, *Rhinoceros antiquitatis* (if we are no longer permitted to call it *tichorhinus*!), and other Mammalia.

The pit is situated on the present floor of the valley of the Lea at a level of about 35 or 40 feet above the Ordnance datum.

In correlation with the archæological stages, the plant-bearing bed of Ponder's End is later than the Mousterien epoch. In fact, it is separated from this epoch by such a wide interval that it is in all probability post-Palæolithic. On the other hand, it is unquestionably pre-Neolithic, although the interval in this case appears to be comparatively short. There is thus little doubt that it comes within the period of the archæological hiatus between the Palæolithic and the Neolithic ages.

It is by far the most important plant-bearing bed that has hitherto been found upon this horizon within the area occupied by Palæolithic man in this country. It occupies a position not represented on the well-known sites of Hoxne or Hitchin. The only bed, so far as I am aware, which can be placed on the same horizon is that at the Admiralty Buildings, Westminster. This, however, only yielded two species of plants, one of them being the Arctic form *Betula nana*.

I am at present engaged upon working out the botanical material from this bed—a laborious task, occupying a large amount of time. I am submitting this to Mr. F. J. Lewis, who has very kindly undertaken its identification. A considerable amount of material has already been examined, and, so far, Mr. F. J. Lewis has succeeded in identifying ten species of plants, with four others doubtful. Three of this number, namely, *Salix herbacea*, *Betula nana*, and *Sibbaldia procumbens*, are distinctively Arctic, while most, if not all, of the remainder have a high northern range, although they are not confined to those regions. Mr. F. J. Lewis defines the assemblage as Late Glacial.

The researches of Mr. Clement Reid in beds associated with the Palæolithic deposits have shown that there have been many oscillations of climate in the south of England since the deposition of the Chalky Boulder Clay. With the evidence of this new bed before us there can be no doubt that the Palæolithic age was closed by a partial return to glacial conditions, succeeding an epoch, or epochs, when temperate conditions prevailed. This conclusion is in agreement with the results of recent work upon the mammalian fauna of the Pleistocene age.

This is not the place to enter further into this discussion. Enough has been said to indicate the importance of this bed in throwing further light upon the climatic changes of the Pleistocene age. It certainly suggests that the archæological hiatus is to be directly associated in the south of England with a final return of glacial conditions of climate.

If this view be sound, as I believe that it is, it seems to be perfectly justifiable to define Palæolithic man as interglacial, even although the last glacial phase above indicated could not, of course, compare in severity with those which preceded it.

A New Theory of the Descent of Man.

IT is probable that some readers may fail to appreciate Prof. Klaatsch's "New Theory of the Descent of Man" at its proper worth owing to the technical terms and obscure descriptions used in the account published in NATURE of November 24 (p. 118). The theory is simply this. The Neanderthal man and the gorilla have continuous supraorbital ridges and similar markings for the insertion of muscles on their skeletons; the Aurignac man (who could pass as a fairly high type of modern humanity) has not a continuous supraorbital ridge, in which he presents a very superficial resemblance to the orang, and has certain muscular impressions on his skeleton somewhat similar to the orang's.

On this basis, which must be admitted to be "flimsy" in the extreme, Prof. Klaatsch builds his new theory and supposes that the gorilla and Neanderthal man are co-descendants of one branch, the orang and the Aurignac man of another. If one were to apply the principles used by Prof. Klaatsch to the canine in place of the human world, then we should say that the rough-haired Newfoundland is a co-descendant of a rough-haired bear, while the smooth-haired mastiff has arisen with the sleek leopard. An explanation is thus given of the points in which the Newfoundland and the bear, the mastiff and the leopard, have in common; but what of the hundred characters which the Newfoundland and the mastiff possess in common, and which separate them from the bear and leopard? Prof. Klaatsch ascribes these to "convergence phenomena." At least that is how he accounts for the fact that the Neanderthal and the Aurignac men have all the features common to humanity; one arose *via* the gorilla and the other arose *via* the orang, but both arrived at the same structural goal so alike that most of us regard them as the same species.

The theory, owing to the demand it makes on "convergence phenomena," passes somewhat beyond the limits of rational speculation. Prof. Klaatsch's theory has failed to gain the support of his able colleagues in Germany, and is not likely to receive serious consideration in this country.

A. KEITH.

Royal College of Surgeons, December 10.

The Cocos-Keeling Atoll.

IN reply to Mr. Wood-Jones's letter (NATURE, December 1), I would say that I still consider that his arguments against Sir John Murray's theory go in support of it.

Mr. Wood-Jones suggests the reason for the precipitation of calcium carbonate, *when it has once begun*, going on until the solution contains less than the normal quantity; what I wished to emphasise was that precipitation does not *begin* until more calcium carbonate than is normally present first passes into solution, *i.e.* that no crystals can be formed in the interstices of the massive corals in the lagoons until some of the dead coral is dissolved. There *is*, therefore, *proof* of solution in the lagoons of atolls.

In an early discussion on the same subject Sir John Murray pointed out that the processes of the solution of the carbonate of lime of dead shells and skeletons by sea water, and of its secretion by the living organisms, are going on side by side wherever there are life and growth, death and decay. In some regions secretion is in excess, and there is a formation of calcareous deposits; in others solution is equal to secretion, as in the red clay areas of the ocean; in others solution may be in excess of secretion, as in the larger and more perfect coral lagoons.

In small coral atolls the periphery is large relatively to the size of the lagoon, and the secretion of lime and the formation of coral sand are greatly in excess of the solution that takes place, hence the lagoon becomes filled up.

In large atolls, on the other hand, the periphery is small relatively to the size of the lagoon; there is less secretion and formation of coral sand by the living outer surface than is removed in solution from the lagoon, which is, in consequence, widened, deepened, and reduced to a more or less uniform appearance.

Positions of Birds' Nests in Hedges.

ABOUT a year ago I wrote to NATURE (December 16, 1909) giving certain facts which I had noticed with regard to the position selected by birds when building. There seemed to be good reasons for such selection, but I wanted to know whether the conditions I had noticed were local or general. The letter sent to NATURE by Mr. A. R. Horwood showed that similar conditions were found in Leicestershire, Shropshire, and Surrey. Of the information which reached me directly, one letter deserves mention.

Mr. Francis G. Cousins enlisted some of the boys of the Johnstone Schools, Durham, as observers. Out of eight nests, the positions of which are given in the terms of my letter, two only faced north, one faced north-west, four south-east, and one south. I quote the following note sent by these observers:—"In the north-east of the district, with fairly open country, the nests faced north-east, and *at their rear was a vast extent of woods.* In the south-east of the district the nests face south-east, *with woods again at their backs* and open country in front." The italics are mine. I need not labour the conclusion that birds seek sun and warmth when building their nests. In this connection it is interesting to quote an observation made by Mr. Roosevelt ("African Game Trails," p. 290). He notes that, in Guaso Nyero, just north of the equator, the weaver birds place the mouth of the nest invariably towards the north, away from the strong, prevailing winds.

J. H. TULL WALSH.

Heath House, St. Faiths, Norwich, December 11.

Tribo Luminescence of Uranium.

I HAVE not seen in recent literature any reference to the "tribo" luminescence shown by uranium salts, and by metallic uranium in particular. Having accidentally knocked over a bottle containing 2 grams of the latter substance, I was surprised to see the bottle glow with a brilliant yellowish-white light, and on shaking the bottle the luminosity could be maintained to such an extent that the label on the bottle was read with ease, and the general illumination seen easily throughout a large lecture-room. The best way to see the glow is to bring the bottle sharply down on the palm of the hand.

On repeating the experiment with compounds of uranium, the nitrate and yellow oxide show the same effect, but to a very much smaller degree, whilst the black oxide and sodium uranate do not give it.

I expect the above must be known to workers with uranium salts, but it may be useful to some of your readers to know a method by which tribo luminescence may be so easily demonstrated.

Grey University College, Bloemfontein, November 18.

MARKED BIRDS IN TWO SENSES.[1]

(1) THE interesting brochure referred to below gives an account of the bird observatory belonging to the German Ornithological Society at Rossitten, which, already well known, is likely to become in the future of prime importance in securing data, by local observations and by the labelling of living birds, towards the determination of many obscure questions in bird migration.

Rossitten is situated on the narrow belt of sand-dunes, lying between Cranz and Memel, which bank out the Baltic Sea from the Kurische Haff, the more northern of the two lagoons chiefly forming the seaward face of East Prussia. The station—mainly designed by Dr. Thienemann, the distinguished ornithologist—was established in January, 1901, and fitted up at the expense and under the auspices of the Ministers of Education and Agriculture. Being, therefore, a State institution, it will possess greater stability than it could have had under the private enterprise of the society alone. Dr. Thienemann is director of the station, and holds with this post that of Custos of the zoological collections of the neighbouring university in Konigsberg. Ulmenhorst, the actual designation of the observatory, derives its name from the generous lord of the manor, Herr E. Ulmer, who presented, in 1907, the present buildings in a new and more favourable site, some seven kilometres from Rossitten, than the original installation. Here Dr. Thienemann and his assistants, cut off from the world, spend the dreary and stormy season of the year from October 1 to May 1. The station stands on the narrowest part of the sand-spit, whence the observers have a free and unrestricted view of the area between the seaward and the inner sandhills, and can study the birds which specially collect there under genuinely natural conditions. Previous observations made along this stretch of sand-dunes, on the movements of the hooded crow (*Corvus corax*), proved that a migration route of great importance passed along it, and that every year it was a rendezvous for flocks composed of the same individuals. The site, therefore, though peculiar and isolated, has been deliberately chosen because of its special advantages.

The chief objects of the observatory are to record the exact dates and composition of the migration flights, with the numbers and age of their component species; the direction in which the birds travel; the velocity and altitude of their passage (to be determined by the use of field telephones and box-kites), and the atmospheric conditions prevailing during its continuance, with the effect of any changes on the migratory stream. Many other cognate questions are to be inquired into, such as bird-life in relation to food supply, moulting, and colour changes in the plumage at different ages, the economical value of birds, and the most suitable means of protecting useful species. It is intended also to form extensive collections of the skins and internal parts of the birds of the Nehrung and neighbourhood for reference and systematic study. The scope of these observations as proposed to be carried out at Rossitten, if covering a somewhat wider field than, does not greatly differ from that undertaken by, the committee of the British Ornithologists' Union and by other observers elsewhere. Valuable as the observations all are, however, they do not, as was pointed out in NATURE of May 26, 1910, seem likely to carry us further forward than we at present are towards the solution of the phenomena of migration, until such observatories are more numerous and widely distributed; for what is now required is to trace individual birds or flocks along every part of their route from their birthplace to their winter quarters, and back again several times. These feathered armies may change their altitude, speed, and direction, or may break up into several battalions beyond the nearest horizon of an isolated observatory, and be affected in front and in rear by weather conditions unobservable from it. Even such bird observatories are as yet few in number. There is one at Riga, one in Algiers, another in Heligoland, and the one, so well known, at Buda-Pesth, which cooperates with an observer in almost

(2) "Aigrettes and Bird Skins: the Truth about their Collection and Export." By Harold Hamel Smith. With a Foreword by Sir J. D. Rees, K.C.I.E., C.V.O., M.P. Pp. iv+138. (London: John Bale, Sons, and Danielsson, Ltd., 1910.) Price 5s.

every Hungarian province. By the more crucial method of bird-marking the Rossitten observers are busily engaged in carrying out investigations which will give us eventually, we trust, the essential data referred to above: the identification of the members of a flock all along its migration route.

Besides those of Rossitten, only a few other ornithologists have attempted the "kennzeichnen" of birds. These are Prof. Martensen in Viborg, Prof. Thomson in Aberdeen, Mr. Witherby in London, and the watchers at the Heligoland station. The "marking" is done by affixing a light aluminium garter, capable of easy and quick attachment to the leg of adult birds captured for the purpose, and of fledglings before they leave the nest. The weight of these rings is so disproportionate to that of the bird that they form (as has been proved) no possible impediment to its flight or feeding. The weight of a stork's ring, for instance, is only 2·4 grammes, while that for small species is only 0·05 grammes. Each ring bears a number and the name of the station embossed on it, and when attached serves as an addressed missive for its return to the station of origin. The latter is obviously an essential factor to the success of the system. At all events, if the ring itself be not returned, its number with an accurate note of the time and place of its wearer's recapture must be communicated to the observatory, or published in some journal likely to meet the eye of the Rossitten or other European ornithologists. Each bird, as soon as ringed, is liberated to assemble with or rejoin its associates in autumn and fare forth on its adventurous voyage. The larger the number of birds ringed out of a migratory flock, the greater are the chances of prizes being drawn in this novel lottery by the man with a gun or a snare, and of data, indisputable and free from conjecture, being accumulated towards the elucidation of the routes followed by the flock, and of the terminus of its journey.

At Rossitten numbers of hooded crows, black-headed and herring gulls, storks, rough-footed buzzards, and various species of Totanidæ, Fringidæ, and Charadriidæ have been ringed since the observatory was established. The success of these experiments has been most remarkable. Large numbers of hooded crows were obtained for marking through the observatory's investigators associating themselves with the crow-catchers who frequent the dunes for the purpose of netting these birds for food. Twelve per cent. of the marked crows were recaptured, and the place of their misfortune plotted on a map, which shows that this species disperses over a wide region to the north and south. The most northern point of recapture was 30 km. from Savonlunna in Finland, and Solesmes in France, the most westerly and southerly; while Prettin on the Elbe was the most southern spot in Germany itself. From Rossitten to Savonlunna the distance is 900 km., to Solesmes 1280 km., and from Savonlunna to Solesmes 2180 km. Recaptures were also often effected in the crow-catchers' nets in the neighbourhood of the East Prussian lagoons, sometimes after the lapse of three or four years, showing that the hooded crows come backwards and forwards to this region. Strange to say not a single marked individual from Rossitten has been reported from the Netherlands.

Space does not permit our referring to any of Dr. Thienemann's other records save that of the stork, which indicates very clearly the great value of the results to be expected by and by from these investigations. The first gartering experiments on storks were made in the Zoological Gardens in Berlin on old and on half-fledged birds. They were so successful that assistance was requested, from those who had access to nests of these birds, in ringing as many individuals as possible. The observatory distributed rings free and post paid to all who requested them, on the sole condition that a list of the birds marked, with a note of the place and date of their liberation, and of the numbers on the rings, be sent to Rossitten. In the first year 1044 rings were distributed to outside helpers. The results were astonishingly successful. First of all it was proved that the storks migrate in autumn, not to the south-west, but to the south-east. On plotting the "find places" of the recaptured birds on a map, the course of their long journey from East or North Prussia, where they were ringed, could be traced out with beautiful regularity to east and south. One was returned from Poland, one each from Damascus, Acco (in Palestine), and Alexandria; one, snared by a native, from Fittrisee, in Central North Africa; one from Rosseres, on the Blue Nile; one out of a flock from Fort Jameson, in Rhodesia; one from the Kalahari desert, 8600 km. from its home, killed for food by a Bushman, who, seeing the ring, threw his prize away in terror as something uncanny! and two from Basutoland, in southernmost Africa, which were nine months old, and had travelled 9600 km. from their birthplace. The dated rings proved also that storks return from between one to three years after leaving the nest to within a distance of their natal district of from 6 to 94 km.

The recapture of certain ringed swallows in the nest in which they were born a year after leaving it raises, by the way, the interesting question: If a young bird of the previous year returns to its actual nursery, where do its parents nest? This system of marking the old and young of migrating species will unquestionably go far to provide data for solving the great mystery of bird-life; but it is essential that it be extended to the northern regions of America and Asia; and be instituted not only there, but in the middle and at the southern extremity of the journey—in Central Africa, in South America, in South China, and in Australasia—a work in which ornithologists, travellers, civil servants, and military officers in these regions could render very important assistance. Nor must the marking be confined to large birds. Passerines, because less conspicuous, and because they are captured in large numbers for food, for cage-birds and as agricultural pests, should be ringed in all holarctic regions in vast numbers while in the nest. The establishment of new observatories in these distant regions of the globe is also a matter of urgency which should be seriously dealt with by the next Ornithological Congress. Chance and happy circumstance will doubtless in time reward such efforts, and return to the expectant ornithologist answers from out of the empyrean to his numerous queries, and will yet, we trust, reveal to him the *causa causans* of the periodical restlessness that impels the novice-bird to start and guides it on its long, dangerous, often fatal, but hitherto untraversed route to winter quarters of which it has no previous knowledge.

(2) The second book on our list is, we fear, rather an apple of Sodom, fair on the outside, but, within, ashes—of gunpowder. It deals with birds marked for a very different purpose from those of Rossitten. It is chiefly made up of contributions by Mr. Harold Smith, reprinted from a paper called *Tropical Life*, of which he is editor, and from the *Times*, by various correspondents, to defend those engaged in the plume trade in the tropics from, as is suggested, attacks behind their backs and in their absence by those "bigoted members of society," "well meaning but badly informed agitators," and "egotistical humanitarians," who are urging the Government to legislate to prevent the indiscriminate slaughter of "plumage birds now

rife in certain parts of the British Empire," and, by prohibiting their import into England, to discourage the wearing of birds' skins, feathers, and plumes.

Of course, the badly informed humanitarians are the ornithologists and the lovers of birds in all parts of the civilised world. These people form, however, a large body of highly educated men and women, who among them have closely studied bird-life in every corner of the globe; and who, entirely disinterested, are possessed of—let us say—*quite* as much common sense, are as little led by "sentiment," and know "the true facts of the case through long years of experience," as well as Mr. Harold Hamel Smith and the feather traders.

The book is full of red-herring trails across the question, and of mean suggestions (*cf.* pp. 31, 41 (footnote), and 56) which are not worth our while to notice, and from which even Sir J. D. Rees, who writes a foreword to the book, dissociates himself. It would be reslaying the slain to discuss the question whether or not the slaughter of many kinds of birds for trade purposes is cruelly carried on or not. "Their [the plumers'] ravages are simply sickening," says Prof. Newton, one of the most accurate and unsentimental ornithological historians that ever lived. The evidence is overwhelming. Nor is it worth while discussing whether or not many species of birds are, through the same agencies, becoming exterminated. That question is also beyond contention. The paper on extinct and vanishing birds, by the Hon. Walter Rothschild, in the Proceedings of the fourth International Ornithological Congress (1905), should be read by those interested in this question, and also the remarks of Prof. Newton on Extermination in his "Dictionary of Birds." "The collection of skins for ornithological museums or fishing tackle," we are told, "is far more likely to exterminate a few rare birds than the millinery trade"—who, we are also told, are "the real protectors of birds"—"ever will be." The great bird collection in the British Museum, the largest in the world, contains probably about 500,000 skins, the result of more than a century's assiduous amassing. The present writer has been witness of that number of humming-birds (chiefly) and other bright-plumaged denizens of the Brazilian woods, all killed in the breeding season, being shipped in one consignment (and that not the solitary one of the season) from Rio de Janeiro to London; and has seen in the Moluccas a single canoe-load brought by native hunters consisting of scores of thousands of the most gorgeous members of the New Guinea avi-fauna spread out like wheat in a godown awaiting shipment to Europe.

Such extensive massacres, in which not only the parents but the nestlings perish, may go on for years and not become very obvious without investigation on the spot; but history shows that the results appear only when it is too late for protective measures to be taken. When a species has been reduced in numbers below a certain point, natural enemies, "red in tooth and claw," and causes difficult to determine, begin to operate, and these complete the ruthless work of man without his further interference. Another good reason for legal regulation of this trade is that, by the extinction of dominant species in a region, the equilibrium of nature is disturbed, and results disastrous to agriculture and in other directions arise. These questions formed the theme of many serious discourses by ornithologists from all parts of the world at the congress held this summer in Berlin. There the concensus of opinion was that measures must be taken internationally to prevent the present wanton slaughter of birds.

The burden of this book is that the plume-traders will suffer great loss by the exclusion of skins and feathers from this country. The same cry was raised by the slave-traders against the emancipators who struck at a "legitimate and honest trade" and "an important industry in this country." One correspondent of the *Times* writes (p. 98) it is "generous of you to offer your columns to both sides of this controversy." Mr. Smith, less generous, excludes all correspondence sent to the same journal on the protectionists' side. From one of the letters he publishes we learn that the feather trade is rapidly going to other countries, for reasons independent of threatened legislation or of interference by "badly informed agitators."

If it be true that the really large part of the trade is done in "the millions of poultry and game-birds' plumage, quills, and tails" (p. 105), why, then, this great outcry against the protection—which the traders say they desire—of the most beautiful and useful of living creatures, since tropical skins form in England so small a portion of the trade. Among the demands of the traders one is protection for the birds at their natal centre only. This the Government to some extent has done, and can do only, in its own possessions; still, its legislation instead of "not securing the preservation of a single bird" (p. 84), is providing, and will increasingly provide, very large areas of sanctuary for them. It would stultify itself if it allowed the importation of feathers from everywhere else, but prohibited it from its own dominions. Another demand is a close season (in India, for instance), after which skins and plumes would be allowed to be exported. As it is in the breeding season chiefly during which the birds don the ornamental plumage for which high prices are paid, it is obvious—human avarice being what it is—that bird slaughter would be carried on surreptitiously during that season, and the results quietly stored away until the closure was over. The expense of enforcing a close season being prohibitive, the next best means of staying the evil is prohibition of export. The "agitation" has been taken up by the Ornithological Congress, and we may shortly look forward to international regulation of the trade.

This book may contain "the truth" about the collection of "aigrettes and bird skins" as it appears to Mr. Harold Hamel Smith; but we conscientiously believe that every unprejudiced, disinterested humanitarian in this country will repudiate his assertion.

A MONOGRAPH OF THE OKAPI.[1]

THOUGH this monograph is replete with exact, and in many cases novel, information regarding the outward aspect and bones of the okapi, it will certainly strike the general reader, as well as the zoologist, as being an incomplete treatment of the subject. This may not be the fault of its principal author, Sir E. Ray Lankester, and is certainly not that of the keeper of the Natural History Museum, Dr. Sidney F. Harmer, but is apparently due to the financial control disliking the expense of publishing the volume of text, which should have accompanied the mere illustrations included in the volume under review. The reason given is that as Jules Fraipont has already published a monograph of the Okapi for the State Museum of Tervueren, Brussels—an admirable piece of work, it is generally admitted to be—the publication of the text of Sir E. Ray Lankester's studies and deductions would be superfluous. It is

1 "A Monograph of the Okapi." By Sir E. Ray Lankester, K.C.B., F.R.S., assisted by Dr. W. G. Ridewood. Pp. viii+48 plates. (London: British Museum (Natural History) printed by Order of the Trustees, Longmans and Co., B. Quaritch, Dulau and Co., Ltd., 1910.) Price 25*s*.

difficult to agree with the propriety of such a decision, and it is to be hoped that before long the text which should accompany these illustrations will also be printed and published, especially as in the interval of time which must elapse, further accurate information regarding this interesting beast may have come to hand. (The present writer has just been advised by Dr. Bumpus, of the Natural History Museum at New York, that a collector sent out by that museum has succeeded in capturing alive a male, female, and calf of the okapi, and these living forms of the animal are now being conveyed across the Congo basin for shipment to New York.) M. Fraipont's work, moreover, complete as it was for the date of its publication in 1908, is not nearly so accessible to ordinary students of zoology as the British Museum publications.

The history of the discovery of this Giraffid form at the very opening of the twentieth century has already been related so frequently that it does not need to be repeated. But the specimens received during the first few years from the present writer and others, left those zoologists who studied them in some perplexity, for they seemed to indicate, when closely compared and examined, the existence of two types, or even species, of okapi. There was considerable difference, for example, in the arrangement of the stripes on the hindquarters between the first strips of skin sent home by myself in 1900 and the complete skin obtained by me with the help of Lieuts. Meura and Eriksson in 1901, and still more in the specimens secured later by the Belgian officers in the Congo basin and a number of British explorers or natural history collectors.

As already stated by M. Fraipont, this variability of the alternations of black and white on the hindquarters and fore limbs must apparently be accepted as a characteristic feature of the okapi, and can scarcely be regarded as of specific value. But then arises the problem of the existence and non-existence of ossicones. Both the skulls sent home by me in 1901 were found to be hornless, though one presented slight swellings of the bones at the base of the nose and above the eyes, swellings to which attention was immediately directed by the whorls of hair in the skin of my large specimen, which suggested that the okapi could develop giraffe-like "horns" on those places. The complete skin and skull obtained for me by Lieuts. Meura and Eriksson, and now in the British Museum, were shown conclusively to belong to an example that was sub-adult, namely, not grown to its fullest size of development. The sex was very doubtful. The natives who brought in the skin seem to have spoken of it as the skin of a male, but it was generally adjudged to be a female.

As soon as attempts were made to transmit okapi specimens to Europe, the zoological authorities in Brussels, London, and Paris were not long in having in their hands skulls of undoubted male okapis possessing ossicones three inches long or more, some of which bore at the tip a small piece of naked bone equivalent to the beginning of an antler. Other skulls, again, supposed to be female, were quite hornless. In some cases, minute ossicones were discovered under the skin. The general conclusions to which zoologists were brought by the imperfect material at their command were: that there were either two species of okapi, one horned and one without horns; or that the comparatively speaking hornless female okapi was larger than the male: for the horned skulls of all the known male okapis are found to be smaller than those of the specimens of hornless females.

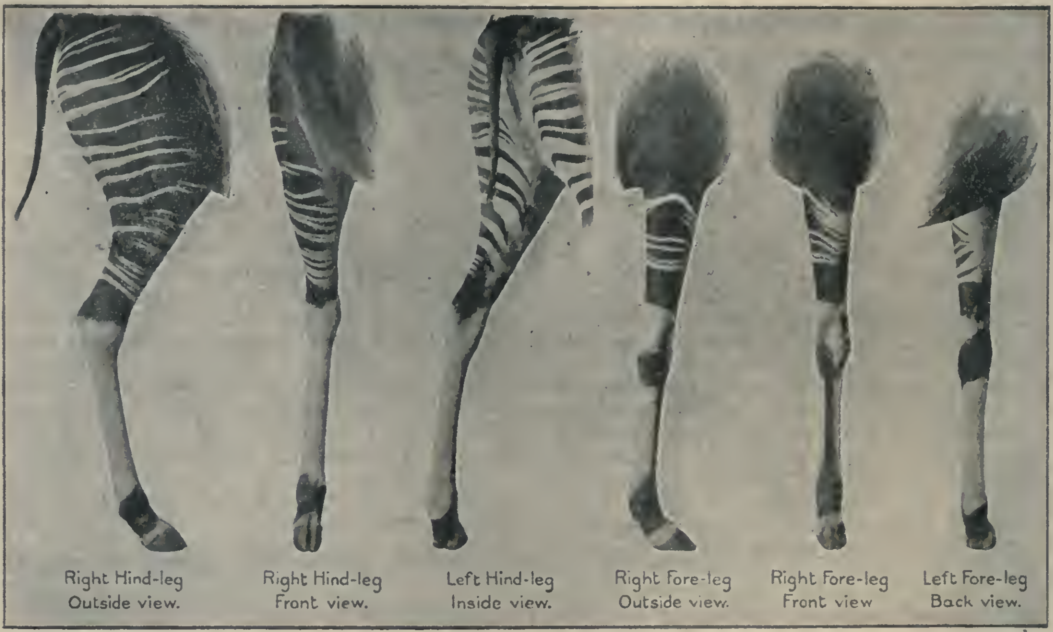

FIG. 1.—Specimen of Okapi in the British Museum (Natural History) presented by Sir Harry Johnston. From "A Monograph of the Okapi."

Then, again, the skulls seemed to be divisible into two series, broad and narrow. The question of two distinct races, subspecies, or species, of okapi (the first known of which was styled *Okapia johnstoni*) can only be decided finally by extended research. M. Jules Fraipont came to the general conclusion in 1908 that there was but one species known to us which he re-named as above, but opined that there might be distinct local races, varieties or even subspecies, within a geographical range, which, although described in the monograph under review as of limited

area, is really not so very restricted after all. The notes and observations of explorers and Belgian officials show that the okapi is met with from the vicinity of Nyangwe, in the eastern part of the Congo basin, at no great distance from the west coast of Tanganyika and from between 4° and 5° south latitude, to the River Welle at the same distance north of the equator, and almost to the banks of the Semliki River and the forests west of Lake Albert Nyanza; while its western range has already been extended (north of the main Congo) to the lower course of the Mubangi River, which lies not far away from the zoographical limits of the Cameroons district. Indeed, it would not surprise me at all if some such explorer as Mr. George Bates discovered the okapi in the Cameroons hinterland, just as he has discovered there the Black Forest pig, and other equatorial African animals first recorded in the East or Central African forests.

Whether the okapi is found anywhere to the *west* or *south* of the course *of the main Congo* is as yet unrecorded, just as we have no record of the existence of any anthropoid ape in the Trans-Congo regions. So far as our imperfect information goes, the main stream of the great Lualaba Congo acts as the limit of distribution of some other forms of mammals, and it may well be that at the time these creatures entered tropical Africa the greater part of the Congo basin was still a vast, shallow, fresh-water sea. A good many of the creatures of the equatorial belt of Africa extend from Mount Kenia and the East African and West Tanganyika forests, right across Uganda and the northern Congo basin to the Lower Niger, the Gold Coast, Liberia, and Sierra Leone, but of this series so far no trace of the *gorilla*, the *okapi*, or the *Black Forest pig* have been met with westwards of the Lower Niger, or even of the Cameroons, though there are Dutch records of the seventeenth century, as well as existing native traditions, which point to the existence of some form of Black Forest pig in the Liberian forests.

INTERNATIONAL MINERAL STATISTICS.[1]

TO the student of mining economics, part iv. of the Mines Report is always a volume of special interest. The publication of Colonial and foreign statistics in the present form was due to the initiative of the late Sir Herbert Le Neve Foster, to whom all interested in mineral statistics owe a deep debt of gratitude. No one, however, was more sensible than Le Neve Foster himself of the many shortcomings of this publication, as the writer of the present review can personally testify, and it is a matter of great regret that so little has yet been done to remedy some of the more glaring of the defects of this publication. It is not to be inferred that the removal of these defects is a simple or an easy matter, or even that it lies within the power of any one individual to accomplish it, for it is highly probable that nothing short of an international agreement amongst the great mineral-producing countries of the world can effect this end, even partially. Such a work as the present has for its main object the comparison of the mineral outputs of various nations, and of the conditions under which this output is obtained, mainly with reference to the labour engaged in its production and the relative danger of the miner's occupation. It is a truism that no real comparison is possible unless similar data are compared, and it is here that the main difficulty lies, the same terms being used in different countries with widely different meanings.

To take a striking example, we find in the introduction a statement to the effect that the death-rate from accidents in coal mines is as follows for the year 1908:—

Per 1000 *Persons employed.*

United Kingdom...	1·32	France	0·95
British Empire	1·45	Germany	2·46
Austria	1·10	United States	3·42
Belgium	1·07	Foreign countries generally	2·34

[1] Home Office. Mines and Quarries: General Report and Statistics for 1908. By the Chief Inspector of Mines. Part iv., Colonial and Foreign Statistics. Cd. 5284. (1910.) Price 1*s.* 8*d.*

This statement is given without comment or explanation, and leaves us to draw the obvious inference that coal-mining in the United Kingdom is attended with considerably greater risk to the miner than is the case with our French and Belgian neighbours. To those who know the true facts, it is, however, by no means certain that this greater risk in this country is a real rather than an apparent one. It is a curious fact that in no country does legislation define what is meant by a fatal mining accident. In the United Kingdom our inspectors have adopted a working definition which answers all purposes, although devoid of legislative sanction, and class as a fatal accident any accident that directly or indirectly causes the death of the victim within twelve months after the occurrence of the accident. In Belgium, however, only those accidents are considered fatal that directly cause death within thirty days of the accident, whilst in France, where no definition at all is attempted, an accident is only classed as a fatal accident if it causes directly the death of the victim, either on the spot or at any rate within a very short interval of time, whilst in Germany and Austria it would seem that for an accident to be classed as fatal it must directly cause immediate death.

It is thus obvious that if the French or Belgian accident list were calculated upon the same basis as the British, the death-rate in those countries might quite conceivably appear to be higher and not lower than our own. When the supreme importance of this matter is considered, and when it is remembered that every one of the countries concerned is engaged in discussing legislation to promote the greater safety of the miner, such legislation being not infrequently based upon the comparative degrees of safety as shown by the ratios of fatal accidents in the different countries, it is surely a pertinent question to ask whether it is impossible to agree upon an international definition of a fatal accident.

Coming next to the statistics of production, a certain degree of uniformity has been attained by expressing all the outputs in metric tons. On the other hand, however, there are unfortunately many different methods in use for estimating the outputs. Beginning with the first mineral on the list, namely, coal, there are many sources of error in the apparently simple task of recording the coal output. Even in the United Kingdom the returns as between different collieries are not comparable, the practice being here to return as output the total weight of mineral drawn up the shaft, regardless of the fact that this may contain more or less stone. So that if of two mines, which produce an equal quantity of coal properly speaking, the whole of the stone is in one case picked out below ground, whilst in the other a good deal of picking is left to be done on a picking belt at bank, the latter will be returned as producing more coal than the former. Again, the question of colliery consumption has to be considered; a certain proportion of the coals raised is used for the purposes of the colliery itself, in order to generate steam for the various engines at work, whilst in other cases, again, some of the miners are supplied free with coal for domestic purposes, this coal constituting in effect a portion of their wages. It is obvious that it will make a considerable difference in the output returns if the colliery consumption under one or both of these heads is included or excluded.

The best plan would probably be to return only the vendible coal as the output of a colliery, in which case the coal supplied to the colliers, and in effect sold to them as part of their wages, should be included, but not that used for raising steam. More important, however, is it to have a definite rule, which rule ought to be clearly and precisely set forth in the returns; some legislative enactment on the subject is obviously required. In Belgium the returns until quite recently were always those of the coal raised including stone; of late years some collieries have, however, returned only vendible coal, whilst others adhere to their ancient practice. In France the return represents the vendible coal *plus* the colliery consumption. In Germany the output returns comprise vendible coal *plus* colliery consumption *plus* a certain allowance for wastage. Further, it must be remembered that on the Continent the coal itself is very often not weighed, but its weight is estimated from the volume *e.g.* from the number of tubs of a known capacity, produced by the mine. Here, again, it is obvious that we are comparing figures which we have no means of reducing to any uniform denomination, and here, again, it is most important that there should be an international agreement as to what is meant by coal output.

Most countries assign a value to their coal production, and in the introduction to the present report the values of the coal outputs of some of the leading producers of the world are tabulated. It is interesting to calculate from this table the values assigned by the various countries to their coal, the figures obtained being as follows:—

United States	5·79*s.*	per metric ton
Great Britain	8·78	,, ,,
Germany	7·91	,, ,,
Austria and Hungary... ...	6·10	,, ,,
France	12·68	,, ,,
Belgium	12·92	,, ,,

It is obvious at first sight that these coal values must be based on more or less arbitrary data, and possess no scientific importance. Intrinsically French coal is certainly not worth more than twice as much as American coal; in fact, so far as absolute value goes, the American coal, which is here returned as the least valuable of all, is actually the most valuable, as a large proportion of high-class anthracite enters into the American production. Undoubtedly the determination of the value of a given mineral production is a difficult matter, even if a precise definition be adopted; it would probably be best to take as a basis the value of the mineral loaded up ready for transport at the mine, or, in other words, its selling price less the cost of transporting it to a market and marketing it; the only drawback to this mode of valuation lies in the fact that the values thus assigned may be liable to wide fluctuations in accordance with the laws of supply and demand. Fortunately, it may be said that of all the data contained in this report, the monetary values of the mineral production are probably the least important.

In some cases, improvements have been introduced in the methods of stating the returns; thus gold and silver are now returned in kilograms of fine metal. In many cases the output of metalliferous minerals is stated, not in terms of the weight of ore, but in terms of the weight of metal contained in the ores. The heading in the report before us says, "contained in or obtained from ore," but we assume that the latter half of this phrase is an error. The figure that is required is either the amount of metal contained in the ore or else that obtainable from it, the two being by no means equivalent statements. If the former is adopted, it means the weight of ore multiplied by the percentage of metal contained in it as determined by accurate chemical analysis, not by so-called commercial assay. If the latter method is adopted, the return would give the amount of metal that can be obtained from the ore by the smelting operations to which it is

subjected in each case; and it is therefore less than the former figure by the smelting losses of various kinds. The latter form of return would be decidedly the more useful, but is the more difficult to obtain correctly. It is, however, essential that one or other of these two methods be adopted, and not sometimes the one and sometimes the other.

The report also deals with the number of persons employed in producing the mineral output of the various countries, and there is perhaps no portion of the statistical records before us in which more divergent methods of enumeration are made use of. Some countries return indiscriminately men, boys, women, and girls, and some Europeans and natives all under the same heading, whilst others separate these categories. In Germany the usual practice is to return the full number of all names on the register, ill or well, at work or idle, working whole shifts or only parts, working throughout the year or only for a portion, as the number actually employed. The present writer does not know with certainty what the practice is in Great Britain, and doubts whether there is any generally accepted practice; certainly there is none that has legislative sanction. Most managers in this country simply return the number of men on their books on the day when the return is made out; a few seem to consider that the number of shifts worked in the year divided by the the number of shifts worked in the year divided by the number of actual working days. A better method probably would be to take as the average number of men employed daily the total number of shifts worked in the year divided by the number of possible working days. A still more exact method has been proposed by some authorities, and is carried out in some places on the Continent, in connection with schemes of insurance, namely, to take the total number of hours worked in a year by the whole of the workpeople employed, and to divide this figure by some standard figure which shall represent the average number of working hours in a year; this average number might for the United Kingdom be taken as 2400, namely, 300 days of eight hours. Obviously here, again, an international agreement is indispensable. Furthermore, it is necessary to decide whether any, and if so, which of the mine officials shall be included in the list of mine workers; the general practice appears to be to include subordinate officials but none of the staff and none of the office employés, but here again much diversity of practice exists.

Further difficulties arise with reference to the classification of mine workings, our distinction between mines and quarries being quite different from that which obtains in other countries. There is no uniformity of practice in respect of the substances which ought properly to be included in a return of mineral output, and it is an open question whether, *e.g.* brick-clay should be included as well as fire-clay, salt derived from sea water as well as rock-salt, and so forth.

Enough has been said to show that the figures in the report before us must be used cautiously, and that it is unwise to attempt to draw deductions from them unless their meaning is quite fully understood in each case. No doubt this fact detracts considerably from the utility of such a report but it need hardly be said that not the slightest blame can be imputed to those responsible for the report for the existing state of affairs. The work of the statician should, however, always be more than the mere unintelligent accumulation of figures, and here there is ample scope for someone who could persuade the principal mining countries of the world to agree upon a common basis for drawing up the essential elements of mineral records.

At the recent International Congress of Mining and Metallurgy, the question of the unification of mineral statistics occupied a prominent position, and, in fact, the only resolution that was thought worthy of being brought before the general meeting, and was unanimously adopted, was to the effect that the congress should urge upon the various Governments there represented the importance of the adoption of an international system. The report just published by the Home Office is only another proof, if such were indeed needed, of the urgency of such a step, and it is greatly to be desired that our Home Office would take upon itself to lead the way in this matter. It has for many years past made a special feature of the collection of international mineral statistics, and it would be eminently appropriate that Great Britain should inaugurate an attempt to arrive at an international understanding; there can be no doubt that the other Great Powers interested in the question would heartily welcome such a step, and that an international commission could easily enough arrive at a satisfactory arrangement. Until this has been done, all the expense, care, and trouble involved in producing part iv. of the "Mines Report—Colonial and Foreign Statistics," must necessarily be to a large extent wasted, since it cannot but fail in giving a proper comparative view of the world's mineral industry.

HENRY LOUIS.

NOTES.

THE *Times* correspondent at Stockholm reports that the Nobel prizes, amounting to more than 8000*l*. each, were distributed by the King of Sweden on December 10 with the usual ceremonial. All the prize-winners were present to receive their prizes and give the statutory lecture, except the winner of the prize for literature, Herr Paul Heyse, who was prevented by his advanced age from attending. The other recipients were Profs. Van der Waals (physics), Wallach (chemistry), and Kossel (medicine).

THE Physical Society's annual exhibition, which is to be held on Tuesday, December 20, will be open both in the afternoon (from 3 to 6 p.m.) and evening (from 7 to 10 p.m.). Prof. J. A. Fleming, F.R.S., will give a discourse at 4.15 p.m., and again at 8 p.m., on some improvements in transmitters and receivers for wireless telegraphy, and Mr. R. W. Paul will give a number of kinematograph demonstrations of some physical phenomena. Most of the leading makers of scientific instruments are sending apparatus to the exhibition.

THE opening address by Dr. Muir, C.M.G., F.R.S., to the South African Association for the Advancement of Science was delivered before a large audience in Cape Town on the evening of October 31, the day of the arrival of the Duke and Duchess of Connaught to open the Union Parliament. The main subject dealt with was "The State's Duty to Science," and the South African newspapers all agree that nothing more important or more suitable for the occasion could have been chosen. The State was viewed in succession as an educationist, a landowner, a health guardian, and as a patron of pure science, and under each head illustrations were given from the past actions and present needs of Cape Colony. The chief part of the address is reproduced elsewhere in this issue. The Minister of the Interior, General Smuts, in proposing the usual vote of thanks, threw out some hope that the day of university reform in South Africa was not

far distant. At the close of the meeting Dr. Muir presented the South Africa medal to Prof. J. C. Beattie, for his magnetic and other work.

THE jubilee of the German Agricultural Society is being commemorated in Berlin this week by a series of meetings. The Berlin correspondent of the *Times* states that at the meeting on December 12 a vast audience in the building of the Prussian Diet listened to the congratulations of the German Emperor, the Imperial Chancellor, the Prussian Minister of Agriculture, and other distinguished personages. In the course of his remarks, the Emperor is reported by the *Times* correspondent to have said:—"Many a seed has been scattered since the society was founded twenty-five years ago, and has sprung up and flourished under the blessings of peace. Admirably have you succeeded in adopting all the advances in science, in botany, in chemistry, in the breeding of animals, and in industry, and so increased the efficiency of German agriculture and raised the value of Germany's soil. Accept my most cordial good wishes for the future. May the agricultural population continue to hold its own as the core of the people, trustworthy in all circumstances, to the advantage and welfare of the Fatherland."

A GENERAL meeting of opticians and others was held in the rooms of the Chemical Society, Burlington House, on Tuesday, November 29, to consider the desirability of making arrangements for the holding of an Optical Convention in 1912. The chair was taken by Dr. R. T. Glazebrook, C.R., F.R.S., as chairman of the permanent committee. A resolution was carried *nem. con.* that, provided sufficient financial support is obtained, an optical convention be held in the spring or early summer of 1912. The main objects of such a convention were specified as being:—(1) the holding of an exhibition of optical and allied instruments; (2) the preparation of a catalogue of optical and allied instruments of British manufacture to serve as a convenient work of reference for all users of optical and scientific instruments, not necessarily to be limited to instruments actually exhibited; (3) the holding of meetings for the reading of papers and for discussions and demonstrations on optical subjects; (4) the publication of a volume of Proceedings, in which these papers would be collected together. The questions of the inclusion of a foreign section and of the scope of the convention and exhibition were discussed, and an organising committee was nominated to undertake the work of making the necessary arrangements for the convention.

THE Agenda Club, which was formally inaugurated by a banquet last week, proposes to organise effort, knowledge, and influence for the purpose of getting things done which need doing for the benefit of the community. The movement first acquired publicity through "An Open Letter to English Gentlemen" in the *Hibbert Journal.* This letter, and the club itself, appeal frankly to the idealism and the goodwill of the best men; but an equally essential characteristic of the club is to organise the altruism of its members with at least as much efficiency as that of the most successful modern business. The club expressly enunciates its need of guidance by scientific men in determining the agenda to be undertaken and in many details of its work. It is a coordinating society, and not one that overlaps the work of other bodies devoted to special purposes. Among other methods to be employed is that of the most extensive publicity. It should be able to win recognition of the importance of scientific education, to spread scientific ideas, and to extend the application of scientific method and results to the affairs of everyday life. It contemplates the encouragement of research, especially perhaps in social science, and its scheme includes groups of associates, among which are mentioned engineering, literature, medicine, and science. In thus applying tested principles and modern methods to the desire to help, which, if sometimes latent, is almost universal, the club is effecting, at a singularly opportune and critical moment, a new "grouping," which may prove a significant step forward in social evolution. There is no entrance fee and no fixed subscription. Money without other support is neither invited nor desired, but cooperation, with or without subscriptions, is both sought and welcomed. The address of the club is 4 Essex Court, Temple, E.C.

THE report of the council of the Scottish Meteorological Society was presented to the general meeting of the society held on December 6. From it we learn that the prize of 20*l.* offered for competition amongst students and graduates of the Scottish universities for the best essay on a meteorological subject has been awarded by the council to Mr. David MacOwan, of Edinburgh University, for an essay on "Observations in Atmospheric Electricity in and near Edinburgh." The council reports with satisfaction that the publication by the Royal Society of Edinburgh of the observations made on Ben Nevis and at Fort William from 1883–1904 has just been completed by the issue of vol. xliv. of the Transactions of that society. This marks the completion of a great enterprise; and it is noted that not only have the observations themselves been printed in detail, but that the four volumes in which they appear contain also numerous papers in which various theoretical and practical aspects of the observations are discussed. It is a matter of further satisfaction that almost simultaneously with the completion of the publication of the Ben Nevis observations the society has, through the generosity of its friends, been entirely relieved from the burden of debt which it had to assume when the observatories were closed in 1904. The following officers were elected at the meeting:—*President,* Prof. A. Crum Brown, F.R.S.; *vice-presidents,* J. Mackay Bernard and Ralph Richardson; *council,* J. Macdonald, Dr. C. G. Knott, Sir David Paulin, G. Thomson, H. M. Cadell, Captain H. G. Lyons, F.R.S., Sir A. Buchan-Hepburn, Bart., G. G. Chisholm, and M. M'Callum Fairgrieve; *hon. secretaries,* R. T. Omond and E. M. Wedderburn; *hon. treasurer,* W. B. Wilson.

CANCER once again formed the subject of the Bradshaw lecture, delivered by Sir Arthur Pearce Gould at the Royal College of Surgeons on December 7 before a large and appreciative audience, which included Prince Alexander of Teck. For three years in succession, 1903, 1904, and 1905, cancer—although the conditions of the endowment mention merely a "lecture on surgery"—was discussed in speculative fashion and in its surgical aspects by one Bradshaw lecturer after another. This was when the modern revival in the investigation of this disease was in its beginnings, and had contributed little that was new or could be properly appraised. Perhaps from the mere fact that all had been said, and said ably, that could be said, perhaps from a feeling that it was unseemly to harp always upon the same subject, cancer has been left alone for four years. It was well to revert to it again, for by doing so Sir Alfred Pearce Gould put himself in the position of being able to assure his hearers that great advances in knowledge have been made, and that the pessimistic views held by those brought most in contact with the disease are giving way before new hopes. The lecturer showed that the four years' respite had sufficed for the results of the comparative and experimental investigation of cancer

to make a deep impression upon the leaders of the surgical profession. He had much to say which no previous Bradshaw lecturer ever had an opportunity of knowing, and much that even his immediate predecessors had not had time to assimilate. The lecture, which appeared in full in both the *Lancet* and the *British Medical Journal* of December 10, will repay the perusal of all interested in this complex problem and the efforts that are being made to solve it.

COMMITTEES have nowadays become quite a usual form for the organisation and supervision of scientific research to take, and investigations conducted under their ægis may at times not redound in full measure to the credit of the actual workers. Therefore, in Sir Alfred Gould's Bradshaw lecture on cancer it is gratifying to note this generous tribute paid to the workers who have raised the English school of cancer research to its present pre-eminent position among kindred organisations abroad. The lecturer said:—"This college, in conjunction with our sister in Pall Mall, by the initiation, control, and housing of the Imperial Cancer Fund, has taken a very prominent part in this movement, and it is a matter of great satisfaction that the researches carried out in our laboratory are universally recognised as having been of fundamental importance. We gladly recognise that all the success which has attended, and may hereafter attend, the labours of Dr. Bashford and his distinguished associates is not due to the association with these Royal colleges, nor to the sources from which the fund has been collected, but to the ability, the wide knowledge, the patience, and the honesty that are associated with the laborious industry of the workers." However excellently committees may be constituted for advisory purposes and for control, they can never replace the initiative and enthusiasm of individual workers. It is gratifying to know that this principle is acknowledged in the investigation of a subject of such great public moment as is cancer.

THE death is announced of Captain G. E. Shelley, the youngest son of the late John Shelley, of Avington, in Hampshire, and nephew of the poet. After a short service in the Grenadier Guards, Captain Shelley retired from the Army and devoted himself entirely to ornithology, especially to that of Africa. Captain Shelley's earliest publication was a "Handbook on the Birds of Egypt," a most useful companion to the voyager on the Nile, illustrated by many excellent coloured plates drawn by Keulemans. He next turned his attention to the sun-birds (Nectariniidæ), and in 1880 completed a beautiful quarto work containing coloured figures of every species of this brilliant family, which may be said to represent the humming-birds of the New World in Africa and Asia, although the two groups are by no means nearly related to each other. In 1890 Captain Shelley was requested by Dr. Günther to join Mr. Sclater in preparing the nineteenth volume of the great "Catalogue of Birds in the British Museum." To this he gladly consented, as among the families included in this volume were the cuckoos and other groups of which he had made a special study. Captain Shelley now planned a general work on the birds of Africa, in which he proposed to comprise an account of all the birds known to occur in the Ethiopian region. The first volume of this important work was published in 1890, and succeeding volumes were issued up to 1906, when the failing health of the author brought the continuance of the work to a stop. Besides these three works, Captain Shelley was for many years a constant contributor to the *Ibis*, the journal of ornithology published by the British Ornithologists' Union, of which he was a well-known member. He was also an excellent field naturalist, and made many excursions to different parts of Africa in order to observe the bird life with his own eyes and to add to his valuable collections, which, we believe, have attained a final resting place in the British Museum.

THE Berlin correspondent of the *Times* reports the death, at seventy-eight years of age, of Prof. Franz König, who held in succession the chair of surgery at the Universities of Rostock (1869), Göttingen (1875), and Berlin (1895). He retired from the latter chair in 1904. His reputation was based largely on his skill in the treatment of articular tuberculosis, on which he published a monograph in 1883 (later edition, 1895). He was also author of teaching manuals of surgery, which were frequently republished.

THE *Aëronautical Journal* for October contained the announcement that the council of the Aëronautical Society had conferred the gold medal of the society on Mr. Octave Chanute, consulting engineer, of Chicago. It was regretted that there was no immediate prospect of his being able to receive the medal in person, owing to the serious illness which overtook him at Carlsbad, from which, however, it was confidently expected that he had recovered after removal to Paris. It is with greater regret that we now learn of the death of Mr. Chanute at seventy-eight years of age. Born in Paris in 1832, Chanute trained as an engineer in America, where his professional duties involved the construction of numerous railways and bridges, including consultative duties connected with the New York elevated railway; wood preservation was also his speciality. From 1874 onwards Chanute became interested in the problem of aviation, and not only did he make numerous experiments with models, but shortly after, or perhaps simultaneously with, Lilienthal and Pilcher's experiments in Europe Chanute took up the practical realisation of gliding flight in America in collaboration with Mr. Herring and Mr. Avery. A large number of glides were made with different types of glider, commencing with a model based on the descriptions of Le Bris's historic "albatross," and including gliders with a large number of superposed planes, but the type finally adopted was a biplane glider furnished with a smallish balancing tail. Although balance was, as a rule, maintained by moving the body, Chanute embodied in his apparatus the principle of a flexible framework, which thus paved the way for the Wright Brothers' "warping" devices and similar arrangements for the recovery of balance and counteraction of instability, which form such a noteworthy feature of modern aëroplanes. The glides made with his machines were remarkably successful, and, the practising grounds being among sand dunes, no fatalities ensued. Chanute was the author of a number of papers and reviews dealing with the flight problem, and the Wright Brothers, the late Captain Ferber, and numerous other aviators were indebted to him for much valuable assistance.

THE annual general meeting of the Royal Agricultural Society of England was held on December 7. It was announced that the total membership is now 10,129, having reached five figures for the first time since 1901. The report, which was adopted at the meeting, contains abundant evidence that the society is assisting scientific research in agriculture in a substantial manner. At the Woburn Experimental Station, in addition to general experiments, trials have been made of the new varieties of cross-bred wheats introduced by Prof. Biffen, of Cambridge, and also of French wheats. The residual values of calcium cyanamide and nitrate of lime have been ascer-

tained in comparison with sodium nitrate and sulphate of ammonia. The pot-culture work has included further experiments on the influence of magnesia on plants. The Hills' experiments concerned chiefly the use of zinc in different forms and of lithium. The question of green-manuring with leguminous and non-leguminous crops respectively has been advanced a further stage. In the botanical department some forty specimens of infected plants were sent for examination. For the most part these were attacked by common diseases, but the following are not so generally met with:—silver-leaf on black currant, Pseudomonas on swede, and Hypomyeces on mushrooms. Two diseases, one on mangolds the other on asparagus, are apparently new to science, and are now under investigation. The society has decided to carry out experiments with calves at the Woburn Farm, for the purpose of demonstrating that by means of isolation it is possible to rear healthy stock from tuberculous parents. Lord Rothschild has undertaken to provide, free of all expense to the society, thirty calves for the purposes of the proposed demonstration. The arrangements are in the hands of a special committee, and Sir John McFadyean has undertaken to supervise the demonstration. With the view of enabling the Royal Veterinary College to make further investigations as to Johne's disease, an obscure disease of sheep met with in certain parts of England, and vaccination as a preventive against tuberculosis in cattle, the council has agreed to make a special grant to the college of 200*l.* per annum for three years, commencing on January 1, 1911.

THE trustees of the Beit memorial fellowships for medical research have elected the following persons to fellowships. We give in each case the general character of the proposed research and the place where it is intended to carry out the research:—*T. R. Elliott*, pathological changes in the suprarenal glands, at the Medical School of University College Hospital. *E. E. Aitkin*, investigation of a group of toxins with respect to the manner of destruction, mode of neutralisation by antibody, and effect of the various modifications upon the animal organism, at the Bacteriological Laboratory of the London Hospital. *Frances Mary Tozer*, the presence of sensory fibres in the third, fourth, and sixth cranial nerves; their influence upon ocular paralysis in locomotor ataxia and other diseases, and the site of the ganglion cells, at the Physiological Laboratory, Liverpool University. *R. W. H. Row*, the structure, development, and functions of the pituitary body in Vertebrata, at (1) King's College, London (Zoological Laboratory); (2) Marine Biological Association's Laboratory; and (3) Naples Zoological Station (collection of specimens and embryological and experimental work). *H. Priestley*, study of the diphtheroid organisms with regard to their distribution, morphology, cultural characteristics, pathology, and relationship to diseased conditions of man and animals, at the Lister Institute of Preventive Medicine. *F. P. Wilson*, the changes in the lipoids of the tissues produced by syphilis and their relation to hæmolysis and immunity, at the Biochemical Department, University of Liverpool. *A. G. Yates*, the bacteriology of acute rheumatism, at the Pathological Department of the University of Sheffield. *Annie Homer*, the chemistry and physiology of tryptophane; the metabolism and chemistry of hæmoglobin in so far as they bear on its production in the animal body; the comparison of normal and pathological tissues as regards their contents of intracellular ferments, at the Physiological and Chemical Laboratories, Cambridge. *F. J. F. Barrington*, investigation of the functions of the male accessory genital glands, at University College Medical School. *J. F. Gaskell*, the origin of the suprarenal body in the invertebrates and lower vertebrates, and on the function of the chlorogogen cells in invertebrates, at St. Bartholomew's Hospital Medical School. The next election of fellows will be held in December, 1911. Correspondence should be addressed to the honorary secretary, Beit Memorial Fellowships for Medical Research, 35 Clarges Street, W.

IN the *Philippine Journal of Science* (vol. v., No. 3) Mr. R. B. Bean gives a further account of his investigations into the different types of ears occurring among the Philipinos, giving on this occasion illustrations of the Iberian and the primitive types. In the former the characteristic features are the inversion of the conch and the rolling out of the helix, this producing a shallow bowl in the conch and a flat helix below. The whole ear is thin, flattened, and usually placed parallel to the head. The primitive ear, on the contrary, is distinguished by the inversion of the conch and the rolling in of the helix, the upper and lower portions of the latter projecting in the form of a shelf, while the conch is deep and bowl-like. The whole ear is thick. In the opinion of the author, ears afford much better race-characters than skulls.

IN the report for the year ending September 20, the committee of the Bristol Museum and Art-gallery expresses its obligation to Lady Smyth for her gift of 1500*l.* to fit up a companion room to the one for which she had previously provided funds. This will enable the adjacent rooms to be arranged in uniformity. Among the additions to the collection is the skin of a giraffe from East Africa, which is now in the hands of the taxidermist, and will in due course be installed in the building.

THE new museum and art-gallery opened at Plymouth on October 25 form the subject of an illustrated article in the November number of the *Museums Journal*. The foundation-stone of a building was laid so long ago as the Diamond Jubilee year of Queen Victoria, but soon after this was done the financial affairs of the city became involved in difficulty, and further progress was stopped. Later on Mr. Andrew Carnegie offered a large sum for the building of a public library, and it was eventually decided to combine with the library a museum and art-gallery, for which funds were provided from other sources. The result is the present fine building, constructed partly of Portland stone and partly of Devonian limestone, with a total frontage of about 320 feet. Of this, the northern 180 feet are allotted to the museum and art-gallery. The whole building is one of which Plymouth may justly be proud.

AMONGST publications recently issued by the International Council for the Study of the Sea are vol. xii. of the *Rapports et Procés-Verbaux*, vol. iv. of the *Bulletin statistique*, and No. 48 of the *Publications de Circonstance*. The first of these contains useful summaries of the fishery work carried out under the direction of the council. Dr. Hoek gives an account of the recent work on eggs and larvæ of the Gadidæ, Prof. D'Arcy Thompson of that on the distribution of the cod and haddock, Dr. Ehrenbaum on the eggs and larvæ of flat-fishes and Dr. Masterman on their later stages, and Dr. Hjort reports on the herring investigations. The statistical bulletin contains a summary of all fish landed in the different European countries in 1907. The last of the three publications deals with the plankton researches, and gives a list of all organisms which have been recorded between 1905 and 1908 on the periodic cruises, with an account of the stations at which they were found. This forms a useful summary of the detailed tables published in the bulletins.

IN an abstract from the *American Breeders' Magazine* (vol. i., No. 2) Dr. G. H. Shull adduces further evidence in favour of a so-called pure-line method in corn breeding that consists in raising self-fertilised generations with the object of developing pure homozygous strains or biotypes, and then cross-breeding from such pure strains year by year.

A NOTE on works of improvement in the forests of the Federated Malay States, contributed by Mr. A. M. Burn-Murdoch, appears in the *Indian Forester* (October). The author distinguishes gutta-percha forests, where *Palaquium gutta* and *P. oblongifolium* are the important species, and mixed timber forests. Under natural conditions the Palaquium forests contain a great number of tall, slender trees in the pole stage arising from an undergrowth of palms, chiefly *Eugeissona tristis*, and shrubs; there are also a few giant trees. When the young trees are cleared of the undergrowth some are unable to support their own superstructure and require lopping, from which, however, they quickly recover.

A PALM disease receiving the name of "koleroga" is described at length by Dr. L. C. Coleman in Bulletin No. 2, issued by the Department of Agriculture in the Mysore State. The disease, confined to the Areca palm, has been prevalent in two separate areas on the west coast of India. For the most part the fruits are attacked, but occasionally the fungus finds its way to the growing apex. Spraying with Bordeaux mixture has proved efficacious. From a study of the sporangiophores, zoospores, and both kinds of sexual organs, and from infections made with the spores, the author concludes that the fungus is very closely allied to the well-known *Phytophthora omnivora*, from which he separates it as a special variety.

THE prominent item in the September number (vol. v., No. 4) of the botanical section of the *Philippine Journal of Science* is the first part of a description, by Mr. E. D. Merrill and Mr. M. L. Merritt, of the flora of Mt. Pulog, the highest, but until recently little known, peak in the island of Luzon. Four zones of vegetation are distinguishable, of which the most important is an open forest belt in which *Pinus insignis* is the characteristic tree; this gives place at an altitude of 7000 feet to a denser forest of irregular trees covered with mosses and lichens, where epiphytic ferns and orchids are abundant, while the summit is open meadow. In the flora the families Polypodiaceæ, Compositæ, and Gramineæ are best represented. There is a predominance of continental Asiatic as opposed to Malayan types, together with a definite, although small, admixture of Australian elements.

MR. BERNARD SMITH has written on the Upper Keuper sandstones of east Nottinghamshire in the *Geological Magazine* for 1910 (p. 302). His study of the characters of these rocks bears out the view, shared by Mr. Cresswell in the paper above referred to, that they were accumulated in distinctly shallow water. "Large tracts with isolated pools were laid bare from time to time." The sandstones among the marls are the deposits of wet seasons, and show characteristic signs of flood and current action. Mr. Smith suggests that the grey or green beds in the Keuper are due to the check on oxidation caused by organic remains and humic and organic acids swept down from the land-surface.

FROM the report of the chief of the U.S. Weather Bureau for the fiscal year 1908–9 we note that observations of the lower strata of air by kites and captive balloons are made daily except on Sundays; efforts are being made to secure materials for kites that will not absorb moisture. Measurements of the intensity of solar radiation and the polarisation of sky light were made whenever conditions were favourable; both appear to have had a higher value than during the previous year. Isobaric charts based on telegraphic reports from selected stations throughout the northern hemisphere have been prepared daily, and successful forecasts for about a week in advance have been issued at intervals; Prof. Moore remarks that the application of world-wide observations and upper-air researches to the art of weather forecasting, both for short and long periods, is yearly becoming more apparent. Reports of marine observations by wireless telegraphy have been discontinued on the Atlantic, but the work has been taken up, to some extent, on the Pacific coast. In the climatological summaries we note that the total precipitation is determined from amounts recorded daily, from midnight to midnight.

DR. L. BIRKENMAJER, of the Cracow University, the author of an elaborate biography of Copernicus, has been fortunate to find (in the "Riks-Arkivet," Stockholm, and in the library of Upsala University) several entirely unknown autographs of Nicolaus Copernicus. The most interesting is a letter written by the great astronomer, on behalf of the Bishop and the Cathedral Chapter of Ermland, on July 22, 1516, to Sigismond I., King of Poland. This message conveys to the King embittered complaints against the Teutonic Order "the Knights of the Cross," described as "praedones, latrones et homines scelerati" in the text of the document, which is entirely in Copernicus's own handwriting. For other interesting details we must refer to the memoir published by Dr. Birkenmajer, in collaboration with the distinguished Upsala scholar Dr. Isak Collijn, in the *Bulletin International* of the Academy of Sciences of Cracow, June, 1909.

THE paper read by Sir Robert Hadfield and Prof. B. Hopkinson before the Institution of Electrical Engineers on Thursday last marks an important advance in our knowledge of the magnetic properties of iron and its alloys. By working in the intense fields obtained between the poles of a large electromagnet they have succeeded in showing that iron and its alloys with carbon, silicon, aluminium, nickel, or manganese have definite saturation intensities of magnetisation which are reached, in general, in fields of less than 5000 units. For pure iron the saturation intensity is 1675 units, and for iron carbide about two-thirds of this. Each alloy behaves as a mixture of one or more magnetic substances with materials having permeabilities not differing much from unity. In annealed carbon steels the saturation intensities are 6 per cent. less than for pure iron for each per cent. of carbon present. The tests of alloys of iron with nickel and manganese have not led to any simple relation between their magnetic properties and their composition.

SINCE Coulomb stated the laws of friction of solids on each other more than a century ago, little work has been done on the subject except from the technical point of view, which does not attach much importance to the absolute cleanliness of the surfaces in contact. The *Verhandlungen der Deutschen Physikalischen Gesellschaft* for October 30 contains a short account, communicated by Prof. W. Kaufmann to the Versammlung Deutscher Naturforscher, of some careful experiments on the subject made by his pupil Miss C. Jakob. The glass or brass surfaces used were chemically clean, and were used in a glass

chamber, which could be evacuated and dried. The observations were made by tilting a large plate of the material with a perfectly smooth surface until a small piece of the same substance, provided with three spherical feet, would slide down the surface. Sliding begins at a very small angle, 1·5° for glass, and the speed has a fixed terminal value for each angle of tilt up to a little more than 5°, when the motion becomes an accelerated one. Up to this point there is a definite relation between the speed and the friction, and this relation must be substituted for the discontinuous law of Coulomb, according to which friction prevents motion until an angle of tilt of the order of 10° or 20° is attained.

AN interesting article on critical speeds for torsional and longitudinal vibrations, by Prof. Arthur Morley, of University College, Nottingham, appears in *Engineering* for December 9. The driving effort of a reciprocating engine, or the resistances to be overcome, may be periodically fluctuating in magnitude, and if the period of such a variation should approach to the period of a free torsional vibration, or to an integral multiple of it, torsional oscillations of some considerable magnitude may be set up, with accompanying high stresses in the material of the shaft. Cases of approach to dangerous resonance with longitudinal vibrations are perhaps much less common in machinery. The author gives a complete mathematical analysis in the article, and concludes with an interesting application to the case of a pit cage and contents weighing ten tons, and being raised by an engine running at 100 revolutions per minute. Taking the net section of the rope at 2·5 square inches and E as 13,000 tons per square inch, the depth at which the natural frequency of vibration of the loaded rope is equal to the speed of the engine is 955 feet, neglecting the weight of the rope. Taking a rope weighing 8·4 lb. per foot, and making allowance for its weight, the depth at which resonance will occur works out to about 862 feet.

OUR ASTRONOMICAL COLUMN.

NOVA ARÆ, 98.1910.—A telegram from Dr. Ristenpart to the *Astronomische Nachrichten* (No. 4457) states that the magnitude of Nova Aræ, recently discovered by Mrs. Fleming, was 9·6 on November 19.

The nova is invisible on forty-four plates of the region taken at Arequipa during the period August, 1889, to March 19, 1910, but appears on twenty-one photographs secured between April 4 and August 3 of this year; on these plates its magnitude apparently ranges from 6·0 to 10·0, and thus it would appear that between March 19 and April 4 the magnitude increased from 12·0, the limiting magnitude of the Arequipa plates, to 6·0. Like most of its class, this nova lies well in the Milky Way, its position (1875·0) being $\alpha=16$h. 31m. 4s., $\delta=-52° 10·4'$.

SATURN'S RINGS.—Herr K. Schiller, writing to the *Astronomische Nachrichten* (No. 4458), states that he observed Saturn's ring system on November 26 at Bothkamp, and could detect no extraordinary feature such as was described by M. Jonckheere in an earlier communication; the atmospheric conditions were excellent, and Herr Schiller employed powers of 200, 600, and 800.

PUBLICATIONS OF THE ALLEGHENY OBSERVATORY.—We have received the first four numbers of vol. ii. of the Publications of the Allegheny Observatory of the University of Pittsburgh, and give brief abstracts of them below. In No. 1 Prof. Schlesinger describes the Mellon spectrograph with which he and the other observers prosecute their radial-velocity researches. This instrument was provided, by the generosity of Mr. Andrew Mellon, for line-of-sight work when the Keeler memorial telescope was completed in 1906. The grave disadvantages arising from the location of an astronomical observatory near a large town, where the sky is never clear and ever illuminated by artificial illuminants, had to be considered when the form of instrument was under contemplation. Consequently, the work which is possible had to be materially restricted, because of the necessity of keeping the possible exposures within reasonable limits, and a one-prism spectrograph was designed. The sacrifice was considerable, but peculiar circumstances rendered it necessary. However, it appeared that useful work might be done if the investigations were confined to such stars as have broad, hazy lines, and this decision has been justified by the results already published. Dr. Schlesinger describes and illustrates the details of the instrument, showing how rigidity has been attained with moderate weight. A region of the spectrum from λ 3930 to λ 4750 can be brought into sharp focus, and under exceptionally good conditions a strong spectrum of a fifth-magnitude star can be obtained in about twenty minutes. Owing to the impurity of the town atmosphere, the large mirror of the Cassegrain reflector has to be resilvered once a month, and the small one every other week; even then, at times, they only reflect about half as much light as when newly silvered, and some 40 per cent. of the deterioration takes place within three or four days of resilvering. The arrangements for maintaining the temperature range of the prism box within 0·1° C., for eliminating flexure, and for adjusting the focus are minutely described and very ingenious.

In No. 2 Dr. Schlesinger and Mr. D. Alter discuss the relative motions of 61 Cygni and similar stars. This discussion indicates that the motion of the companion star is orbital rather than in a straight line—that the two stars are physically connected; thus the designation "of the 61 Cygni type," as indicating pairs not physically connected, should be abandoned.

No. 3 contains a discussion of the orbits of the spectroscopic components of ϵ Herculis, by Dr. R. H. Baker, determined from seventy-two plates taken with the Mellon spectrograph during 1907–8. The period is found to be 4·0235 days, and the orbit nearly circular; there is no substantial evidence for the presence of a third body. In No. 4 Dr. Baker discusses the orbit of 1 H. Cassiopeiæ, from fifty-seven plates secured during 1908–9, and finds the period to be 6·067 days.

THE ORBIT OF THE PERSEIDS.—Meteoric astronomy is being, and is likely to be, considerably advanced by the energetic and organised observations of the Antwerp Société d'Astronomie. Since 1896 the Perseid and other showers have been independently observed at many stations, and the results collated and discussed. During 1909 and 1910, 485 and 303 Perseid trails were recorded, and indicate the existence of seven radiants. For five of the best marked of these M. Henri Dierckx has calculated elliptic elements, which he compares with Hayn's elements for Tuttle's comet, 1862 III., in an article appearing in Nos. 11–12 of the *Gazette astronomique*. The agreement is well marked, although, as the author remarks, the probably large area covered by the swarm of meteoritic particles precludes the expectation that the Perseid elements would rigidly agree *inter se*.

DEFINITIVE ELEMENTS FOR THE ORBIT OF COMET 1904 II. (1904*d*).—This comet was discovered by M. Giacobini at Nice on November 17, 1904, and was observed until May 2, 1905. Herr J. Sedláček has now discussed 118 observations, referred to eighty-four comparison stars, and publishes the resulting orbital elements in No. 4453 of the *Astronomische Nachrichten*. The orbit appears to be hyperbolic, but the departure from a parabola is so slight as to be practically negligible.

DESIGNATIONS OF NEWLY DISCOVERED VARIABLE STARS.—In No. 4457 of the *Astronomische Nachrichten* the commission of the AG Catalogue of Variable Stars gives the permanent designations to 126 recently discovered variable stars. Many of the objects have been discovered to be variable during the present year, whilst the variability of others was detected during preceding years. In addition to the designations, the commission gives the provisional numbers, the positions for 1900, the range of magnitude, and remarks concerning the discovery, the period, the type, and the spectrum of each object.

THE TRANSANDINE RAILWAY.

It was on March 29, 1835, that Charles Darwin, who had reached Mendoza from Valparaiso by Peuquenes and Portillo, set out on his return journey across the Andes by the more northern line of the Uspallata and Cumbre passes, which has always been the principal means of communication between the pampas and the Pacific Coast. It was not until twelve days later that he reached Santiago, though no doubt a less ardent geologist might have completed the journey in somewhat shorter time. It could now be easily accomplished by rail in less than the same number of hours.

FIG. 1.—Valley of the Rio Mendoza below Puente del Inca, looking up stream; the rack rail is seen in the foreground.[1]

The Transandine railway is constructed on the metre gauge, like many of the Indian lines, although it links up two broad-gauge systems. Leaving Mendoza, where it connects with the Argentine Great Western at a height of 2700 feet above the sea, it turns southward across the plain, making for the point where the Rio Mendoza leaves the eastern or Uspallata range of the Andes, and then follows the windings of the deep river valley through the mountains. It thus takes a route somewhat to the south of that by which Darwin and other travellers crossed this range. According to their descriptions, the eastern slopes are composed of Rhætic sandstones and bituminous shales resting on Devonian and Ordovician slates, such as are found in many parts of the Andes. These are covered unconformably still further to the westward by thousands of feet of acid and basic lavas and tuffs interstratified with sandstones and carbonaceous shales, and believed to be of Tertiary age. Intrusions of granite and porphyry also occur.

After emerging from these mountains and traversing the Uspallata Pampa, a plateau of coarse detritus at an altitude of 6000 feet, the railway enters the central cordillera of the Andes by the deep gorge of what may still be called the Rio Mendoza, though, like most South American rivers, it is known by different names in different parts of its course. Here the slates are covered apparently conformably by a thick succession of Mesozoic rocks described in detail by Darwin, Stelzner, and Schiller. They include acid lavas and tuffs, breccias and conglomerates of the same material passing into arenaceous rocks, amygdaloidal basalt, limestones, gypsum interstratified with red and purple sandstones and conglomerates, and finally lava flows, tuffs, and conglomerates, consisting mainly of andesite, which are probably of late Cretaceous or even early Tertiary age. Although marine fossils of Jurassic and Cretaceous types are met with, some of the beds were probably laid down under continental conditions. On the east the rocks are much disturbed, and are penetrated and metamorphosed by granite and diorite, as well as by minor inclusions, which traverse, not only the stratified, but the plutonic rocks.

The sides of the gorge present magnificent sections of the geological structure, one of the finest of which is at the mouth of the Horcones valley, by which Aconcagua was successfully ascended. At Las Cuevas, a little further on, the train enters the tunnel beneath the Cumbre ("summit") pass and emerges in the valley of a tributary of the Rio Aconcagua, which makes its way westward to the Pacific. The tunnel is less than two miles long, and little more than 10,000 feet above the sea, while the pass is some 2000 feet higher. It is stated to have been excavated in limestone and gypsum, and conglomerates of rocks of igneous origin. The western slopes of the ridge are exposed to the wet north-west winds, and the rocks are in places saturated with water and decomposed, so that it was necessary to face the interior of the tunnel with concrete.

The railway then follows the valley of the Aconcagua,

FIG. 2.—Scenery on the Chilian side of the tunnel.

where the later volcanic rocks dip at moderate angles to the westward, and are penetrated here and there by intrusions of "porphyry," down to the fertile plain of the same name, where at Santa Rosa de los Andes it connects with the State railways of Chile. On account of the steepness of the valley slopes and the decomposition of

[1] The illustrations are reproduced, with permission, from a paper by Mr. W. S. Barclay in the November number of the *Geographical Journal*.

the rocks the construction of the line on the western slope presented serious problems to be solved, and the central rack rail is almost continuously employed for a distance of fifteen miles, while on the Argentine side it is only occasionally resorted to.

Nearer the equator, where south-easterly winds prevail, there are railways which, starting from the Pacific Coast, reach an altitude of more than 14,000 feet without the use of any special appliance of this character, for the rainless western slopes present comparatively few engineering difficulties; but when the time comes for railways to be built down to the Amazonian plain it will be no easy task to construct a firm track through the deeply dissected country, where the almost continuous rain has decomposed the rock to a considerable depth, and from time to time great landslips leave a strip of the valley-side denuded from crest to base of its thick covering of trees.

The opening of this through route from the Atlantic to the Pacific is an important step in the development of communications in South America. Soon the Argentine railways will be united to those of Bolivia and Peru, and the lowlands of Bolivia rendered accessible by the railway round the cataracts of the Madeira. Everywhere the plateau, the pampa, and the forest are losing their remoteness and their solitude, and bid fair to be occupied, ere long, with a population drawn from European sources, a consummation that, however natural and inevitable it may be, cannot but inspire some vain regrets in those who have known them when they were still in the state in which the early Spanish adventurers found them.

JOHN W. EVANS.

EVOLUTION: DARWINIAN AND SPENCERIAN.

ON Thursday, December 8, the Herbert Spencer lecture at Oxford was delivered by Prof. Meldola, F.R.S., the title of the lecture being "Evolution: Darwinian and Spencerian." Prof. Meldola began by pointing out that while Oxford had influenced Darwin through Lyell (whose reputation, however, was made by throwing over the doctrine of his old master at Oxford, Buckland), it had also influenced Spencer through both Lyell and Mansel. Evolution, the lecturer proceeded, did not stand or fall with natural selection, but the prominence given by Darwin to the latter principle availed to convert Spencer from exclusive Lamarckism. Darwin and Spencer approached the problem of evolution with different types of mind, and addressed themselves to different audiences; the special task of Spencer was to show that organic evolution was a particular case of general evolution. In this he entirely succeeded, points of objection that might be taken to his views being of minor importance. Selection, so far, had only been shown to prevail in relation to the phenomena of life. Darwin's influence in departments where selection is not found was only indirect.

There was a fundamental difference in the method of attack of scientific problems adopted by Darwin and Spencer respectively. The procedure of the former was analytic, that of the latter synthetic. For Spencer, philosophy was unified science. His treatment of scientific questions was characterised by extreme breadth, inasmuch as his principles transcended the data of particular sciences, this being one reason why he failed to impress scientific men so much as might have been expected. No such attempt to wield the weapon of unified science had ever before been made. In estimating the comparative validity of the methods employed by the two men, it should be remembered that Darwin was working at a lower level; thus his foundations were more securely laid; and however sound the method, information can, after all, only be acquired by beings of finite intelligence and imperfect sense organs. Hence mistakes could be, and actually were, made; these, however, the same method would be competent to correct in the presence of better information. Spencer's plan, on the other hand, was to prove the existence of underlying principle controlling all the processes of nature. Hence his method was philosophical in the more enlightened sense of that term—the sense seen in the old expression "natural philosophy."

From this point of view the division between sciences, though convenient, is arbitrary. The *rôle* of the philosopher is to develop generalisations and present them for verification by science. Hence the sphere of science is different from that of philosophy; and in the region of physical phenomena the deductive method has never been called in question. In conversation with Darwin, the lecturer was once speaking of the difficulties attendant on the interrogation of Nature, to which Darwin replied, "She will tell you a direct lie if she can"! It could not justly be said that Spencer was not an investigator at all; we were apt to forget that we stand on the shoulders of our predecessors, and to judge them by the standard of our own appliances and attainments. Of recent applications of the genuine deductive method, none was more remarkable than the quantitative biometric investigations originated by Sir Francis Galton, pursued by the late Prof. Weldon, and now being carried into various departments by numerous workers with conspicuous energy and success.

The lecture was listened to with marked interest by a large and representative audience, including the Vice-Chancellor of the University, with several professors and heads of colleges. It is published in full by the Clarendon Press.

THE WORK OF POLYTECHNIC INSTITUTES.

THE Lord Chief Justice, Lord Alverstone, G.C.M.G., P.C., distributed the prizes at the annual prize distribution at the Northampton Polytechnic Institute, London, E.C., on Thursday, December 8. In the course of his address, after the distribution of the prizes, he remarked that one reason why perhaps years ago we had fallen back was that this country and this metropolis had not then been aroused to the necessity of thoroughly good technical education, but that now immense good had been done to all the outlying districts of the metropolis, as well as to the City itself, by the establishment of the great polytechnics and by their capability for doing good work and of leading their students to higher and better grades. With reference to the proposed establishment of a great institution of technical optics in connection with the Northampton Polytechnic, he recalled a visit he paid years ago to the workshops of Messrs. Beck, and was satisfied that with the development of science that was now going forward practical optics would take a very prominent place in the future; he hoped that the polytechnic, with the support of those interested in it and the support of public bodies, would be able to say next year that the building of the new optical school had been commenced. It was always, he considered, a matter of regret when the educational facilities of any branch of technical industry were cribbed, cabin'd, and confined, and he further expressed the opinion that it was of very great importance that any school of practical technology or practical instruction in any expert business should be able to command the best apparatus and the best accommodation, because if it did not it would soon take second place. In these days specialisation is absolutely necessary in every trade, and after the preliminary training in fundamental subjects the time soon comes when specialisation must begin with the students, for in the present day it is no good scratching at a subject, but it must be gone through right to the bottom, so that the higher branches may be developed. Rapid modern developments, for instance, in electricity are constantly calling upon the institution for better apparatus, upon the teachers for greater acquirements, and upon the students for greater application.

After reference to the expenditure of some 6000*l.* on the new electric generating station, the Lord Chief Justice reminded the governors that they must be prepared for change if they desired to keep up the standard of the institution to the highest possible point. They must be on the look-out in each subject for the particular branches which can be specialised. In speaking to the students of the necessity for concentration on the object in view, he remarked that the extraordinary thing about Faraday was that he seemed to be able to think and think only of the particular subject that he was studying, and if he saw a light by the way which perhaps might lead him to some other aim or object he did not follow it up at once, but made a note, so to speak, in his mind, never forgetting the main object at which he was aiming, but putting a little mark so as to

come back some day and explore it. The address concluded with appreciative remarks regarding the social and recreative work of the institute, and especially with respect to the high place taken in gymnastics. The necessity for laying up for themselves a store of health and strength was strongly impressed upon the students, and the inestimable advantages of the social intercourse made possible by the existence of the various clubs and societies was insisted upon.

CERTAIN PHYSICAL CHARACTERS OF THE NEGROES OF THE CONGO FREE STATE AND NIGERIA.

IN a lecture at the Royal Anthropological Institute on November 29, Dr. Arthur Keith dealt with the physical characters and relationships of certain negro tribes in Equatorial Africa. His account was founded on data collected by (1) Mr. E. Torday amongst tribes in the Congo Free State, including the Bushonga, Basoka, Sango, and several others; (2) by Mr. P. A. Talbot in southern Nigeria, including the tribes of the Ekoi, Kabila, and Korawfs. Dr. Keith had also at his disposal three collections of crania, an extensive one of the Batatela (a tribe towards the eastern part of the Congo Free State), which was brought home by Mr. Torday; another from southern Nigeria, which he owed to Mr. P. A. Talbot; and a third (from the delta of the Niger) which had been placed at his disposal by Dr. Frank Corner.

In British Nigeria there are several types, but the one which he regarded as characteristic was represented by individuals of low stature, relatively long-headed, with the skull decidedly flattened from side to side. Many of the physical characters of this Nigerian type can be recognised in the Sango and other Congo tribes bordering on the Sudan. In head form, although not in stature, the Dinkas and Furs of the Nilotic tribes resemble the Nigerian type. In a contracted type which is prevalent in the Congo Free State, and which may be called the Congoese type, the head bulges laterally in the parietal region, and is relatively short and low.

The Batatela and the Basoka are representative of this type. It occurs also in some Nigerian tribes, and also in the Nyam-Nyam and Baran tribes of the Sudan. The Korawfs, a Nigerian tribe near the borders of the German Cameroons, are of a low stature with relatively long arms, as in Sir Harry Johnston's "forest negro type," but in head-form they resemble the Nigerian type of negro. The Bushongo from the south central part of the Congo Free State are tall compared with the Korawfs, but possess the massive head, great span, and large nose of the "forest type." In many features the Bushongo are related to certain of the Sudan tribes, such as the Nyam-Nyam. To account for the present distribution of physical characters among the negro tribes of Equatorial Africa one must assume that there has been a free intermigration of tribes, and that in their evolution the tendency in one tribe has been towards the accentuation of one set of features, in another tribe of another set of characters. Thus in the Nilotic Dinkas high stature and narrow-headedness have become marked characters; in typical Nigerians low stature and narrow heads; in the Bsoka a wide, short head and low stature; in the Buruna a wide head and high stature. Interbreeding may have played a part in the determination of tribal characters; if it had played a great part we should have found a greater degree of physical uniformity. The extent to which an admixture of Arab blood has modified the physical characters of negro tribes has probably been exaggerated.

SCIENCE AND THE STATE.[1]

IN all ages the welfare of a State must have been in a greater or less degree dependent on the development of its material resources and on the vigour and intelligence of its people; it is only in comparatively recent years, however, that recognition has been given to the fact that the State must leave nothing of this to chance, but must set itself deliberately by the use of scientific method to make the very best of its resources, and to increase the available vigour and intelligence of everyone within its borders. Not only so, but it must take suitable precautions that intelligence be universally trained, and be also duly organised so as to give the most effective and productive result. It is no longer enough that the State shall merely welcome and applaud a discoverer when he arises, or merely safeguard a private inventor from being fleeced; on the contrary, it must give of its substance to foster both discovery and invention, and must give legislative help to secure that inventions when made shall not be unfruitful through want of skilled labour or other hampering cause.

If we ask the reason for this change, the answer is that the keenness of international competition has vastly increased, that this has led to serious searching of intellect, that the laws of evolution have in consequence been seen to be applicable to nations as well as to individuals, and that under these inexorable laws the very existence of a State may be imperilled by ignorance or neglect. It is thus more important than ever that statesmen and leaders of the people shall not only be men of probity and high general character, but men of wide knowledge and penetrating forethought. They must have studied and must know all the possibilities of both land and people. On the material side they must have reckoned up the mineral resources, the agricultural resources, the water power and other forms of potential energy, the harbour accommodation, the waterways, and the advantages of the geographical position for over-sea commerce. On the human side they must have noted the natural gifts and weaknesses of the people, the best means of developing the former and of correcting the latter; and if it should be that there are varieties of race and colour in the population they must have thought out plans, not only for preventing loss of power through internal friction, but for obtaining the close cooperation of all the races in the general national interest. In the future it is only in a relative sense that there will continue to be "hewers of wood and drawers of water"; the State that aims at being in the forefront will have to see that even its wood-hewing and its water-drawing are done intelligently and to the best advantage. Further, the exploitation of any race in the interest of a higher race will be fatal folly when the need exists for exploiting all races in the interests of the State.

These considerations make it readily appear that the first great duty of the State towards science is to provide an effective and comprehensive system of national education. In the lower stages of the system direct and formal instruction in science need not bulk very largely; what is essential is that the pupil shall throughout his course be trained to observe, to think, and to reason. In the middle stages—the stages covered by secondary schools of all classes—the actual study of science, and especially of scientific method, must form a larger and ever-increasing part of the curriculum. Under neither of these heads, however, need we enter into detail to-night; it is sufficient for our present purpose to insist in connection with both on the desirability (1) of fostering rather than repressing the natural curiosity of the young; (2) of constantly recurring to the study of things in supplement to that of words; (3) of training the hands in the use of appropriate tools other than the pen; (4) of gradually introducing research methods into class-room work. It is the neglect of this advice that has been a main cause in the retardation of science; it has also helped to make school life a byword for dulness, and in many cases made the after-life unintellectual and even trivial.

When we come to the higher stages—the stage of the university, and more practical institutions coordinate therewith—the interest in our subject naturally increases, for there we look, not only for instruction in science and training in scientific method, but for a steady flow of fresh contributions to the stock of human knowledge. That this last is a legitimate expectation is now the received opinion throughout the whole civilised world. In accepting it, too, we have but returned to the original conception of a university—a conception that in the course of a long period of years had gradually come to be forgotten in English-speaking countries. The evil results of

[1] From the presidential address delivered before the South African Association for the Advancement of Science on October 31 by Dr. T. Muir, C.M.G., F.R.S.

this period of somnolescence at length became so striking, not to say alarming, that in May of 1870 a Royal Commission was appointed in England to make inquiry into the whole matter. It may safely be said that no stronger commission ever sat on a cognate subject, and that its long series of reports are models of clear statement and wise counsel which even to-day it would be difficult to improve upon.

"We have no doubt," one weighty report says, "that for a professor the duty of teaching is indispensable, but we agree that original research is a no less important part of his functions. The object of a university is to promote and to maintain learning and science, and scientific teaching of the highest kind can only be successfully carried on by persons who are themselves engaged in original research. If once a teacher ceases to be a learner it is difficult for him to maintain any freshness in the subject which he has to teach; and nothing is so likely to awaken the love of scientific inquiry in the mind of the student as the example of a teacher who shows his value for knowledge by making the advancement of it the principal business of his life." How far the great English universities then fell short of the ideal here indicated may be gathered from the writings of the time. On the monstrously developed examination system much of the blame had, of course, to be thrown. When it was asked what the universities did with their endowments and equipment, a voice from Cambridge said "they perform the functions, for too many of their students, of first-grade schools merely, and that in a manner about which opinions are divided; and superadded to these is an enormous examining engine, on the most approved Chinese model, always at work." Another writer advised that in order to be honest the university ought to put up a large brass plate with the inscription "Examinations held here"; and there were endless other well-deserved sarcasms from those who knew the facts best.

Of the agitation, the inquiry, and the plain speaking much good came, and the English universities of to-day show in consequence a very different character and spirit. The difference may not be all that earnest reformers still desire, but who in South Africa can with any conscience throw a stone at the offenders? Even so late as 1901, when numerous reforms had been effected in England, a great educationist and chemist, in directing attention to the function performed by universities on the continent of Europe, wound up with the passionate cry:—"Their universities have always been schools of research, of inquiry; unless, and until, ours become such, and our youth can be trained to advance, there can be no hope for us. God help us to make the change before it is too late!" If this be the prayer considered suitable for England when the present century began, what petition will suffice to-day for South Africa, which, as regards university research, stands well in the rear of the England of forty years ago? Are we to be encouraged to hope that one result of this year of union will be a serious effort to uproot our low ideals of university work, and to sow in their place the seeds of true learning and research? Fortunately, in one or two of the "colleges" a few individual teachers have set an excellent example, striving so far as their scant leisure permitted to advance the boundaries of their subject. All honour to them, and may more and more of their students imbibe their spirit and unite to press on the question of university reform and the removal of a deeply engrained stigma.

Coordinate in a sense with universities are public museums and libraries, the link of connection being that, besides intended for the promotion of research, they have other purposes to serve. All of them profess to aim at the instruction of the people; but in the case of museums and libraries this instruction is avowed to be mainly of a popular character, and in the case of museums it often differs very little from that more or less elevated amusement called sight-seeing.

As regards "museums," especially local museums, we have to note that, in the first place, very seldom have their founders had the purposes of real research in their minds. Usually, indeed, the original object has been the formation of a collection of animals, plants, and mere curiosities, with the result that if anything profited thereby it was natural history and archæology alone. Further, a fresh museum has almost uniformly been started without any intention of supplementing or cooperating with those already in existence; much loss in effectiveness has thus been sustained. How best to remedy these initial defects has been a long-standing problem with scientific men, and it is now fairly well agreed (1) that the museums of a country should for purposes of coordination and cooperation be under some common control; (2) that while in local museums appropriate specialisation should be encouraged, no science should be wholly neglected; (3) that both of the main purposes, instruction and research, should receive adequate attention in all museums; (4) that in the case of the central museum the purpose of research should be paramount, all the chief officers being chosen because of their ability to advance the knowledge of their own subjects. We in Cape Town have in the South African Museum, with its annals, a scientific agency of great national value and of immense promise for the future. Sad it is to think that, while its collections have been rapidly growing in magnitude and importance, the accommodation for exhibiting them remains as it was fifteen years ago.

As regards libraries, the state of matters is not greatly dissimilar. There are more of them it is true; but if the list be arranged in order of merit we have not got far down it when we find that we have parted company with scientific research. Indeed, the libraries that cater for anyone else than the so-called "general reader" are exceedingly few in number; cooperation is thus at least as necessary as in the case of museums. This is especially true in regard to scientific journals and the publications of scientific societies. The number of these is nowadays so great that a long purse is necessary for the maintenance of a complete collection; but by neglecting cooperation we make matters worse than they need be. Here in Cape Town, for example, we have four or five libraries that purchase scientific serials, and, though the libraries are within short distance of one another, duplicate and triplicate copies of some journals are to be found on their tables, while other journals equally important are neglected by them all. The time surely cannot be far distant when this will be rectified, when the importance of such reference libraries will be better appreciated by the State, and when the South African Public Library, having its special annual grant for reference books restored to it, will take the lead in a scheme of cooperation calculated to meet the wants of all engaged in scientific or literary research.

When thus dealing with the functions of universities, museums, and libraries, I have been in a manner viewing the State as an educationist. I now wish, in the same way, to invite your attention to the State as a landlord. With an extensive and varied property calling for development, one of the first and most urgent duties is to have it surveyed and inventoried under every needful heading. In the first place it must be accurately mapped; in the second place its surface constituents and rock formations must be ascertained and registered; in the third place the animal life of every district must be put on record; in the fourth place the same must be done with its plant life; and, lastly, its water supply, rainfall, and other climatic factors must be observed and tabulated. There thus arise as necessary scientific departments of the State's work—the topographical, geological, zoological, botanical, and meteorological. The fact that some of these subjects are incidentally dealt with by college lecturers and private students is no satisfactory reason for negligence on the part of the State. All such outside aid, it must be remembered, is subject to the uncertainties of personal liking, fashion, and caprice, and, consequently, is in its nature fitful and untrustworthy in an emergency. Besides, much of the work wanted to be done requires continuous attention over long periods, so that efficiency can only be secured by the existence of a permanent staff.

Attention has next to be directed to the State's duty in a third capacity, namely, as general health guardian. Fortunately this, though involving consideration of a number of sciences (entomology, bacteriology, mycology, &c.), need not be enlarged upon, it being self-evident that the bodily and mental fitness of the people is all-important in the life struggle of nations, and that it is almost equally momentous that animals and plants useful to man should be protected from the ravages of disease. Further, there

is the satisfactory reason that in dealing with such matters South African Governments have been, on the whole, sympathetic and, in some directions, markedly liberal. Here again, however, and perhaps in a special degree, it is necessary to give warning that the State should not burden itself with work proper to individuals and private corporations, but should confine itself to needful scientific work which other agencies cannot accomplish. It should never be forgotten that the State which discourages self-help is undermining its own strength.

Thus far we have been considering sciences with direct practical applications; indeed, the reasons for considering them at all has been in the main because of the existence of these applications—because the sciences bear more or less immediately on the welfare and prosperity of the State. What, then, are we to say of sciences from which the State or its people cannot hope to obtain any immediate benefit? Our answer is—and it ought to be given with entire frankness—such sciences must be content to take a second place. The State, we feel, has a perfect right to expect something tangible in return for its outlay; and, its supply of funds being limited, it is bound to pass in review before it any proposed series of scientific schemes, separating them out into practical and impractical, and thereafter sifting the practical into those that are urgent and those that are not. A manifest danger, however, besets the discriminators between rival schemes, it being far from easy to foresee what particular research will prove fruitful of practical applications and what will not. How often has one seen the pure mathematics of to-day change into the applied mathematics of to-morrow, and the previously despised insect collector being hailed shortly afterwards as a benefactor of mankind! All that one can hope for is that those with whom such decisions rest will always take the best advice available. Of recent years European Governments have tended more and more in such cases to consult their great leading scientific corporations; the Government of the Union may in like manner find our own Royal Society a willing and useful guide. I would merely add as a fact worth ruminating on that the States which have differentiated least between pure and applied science are the States which lead the world to-day.

While thus whole-heartedly urging the great importance of science on those who may be called to administer the affairs of State, it would be unfair to ignore the difficulties and troubles which well-disposed administrators are said to have experienced in their dealings with scientific men, or "experts," as they prefer to call them. The complaint of the most moderate of these critics is that the man of science is normally unpractical, and that his value to the State is marred by eccentricities due to over-study or excessive specialisation; and those critics who are not moderate, and who love a biting phrase better than strict accuracy, say that when he is not an astute self-seeker he is either a mooning pedant or a pernicious crank. Now in regard to this I should first wish to ask whether it be not the case that the failure of the scientific expert is often due to causes wholly outside himself. Time and again one has seen a man chosen for his high qualifications in a special branch of knowledge, and then set, not to the work of extending this knowledge by investigation, but to the absolutely diverse work of "running" a Government office or carrying on a purely business undertaking. Failure, nine times out of ten, is thus inevitable, so rare is it to find the successful student and the capable administrator combined in one. Surely it is the merest common sense to urge that if both sets of qualifications be wanted, reasonable care should be taken either that they are possessed by the same individual or that a practicable arrangement involving their separation has been previously devised. One thing certain is that in particular the appellation "self-seeking" as applied to men of science is singularly unfortunate, for, though the man of science with such a bent is not unknown, one's whole experience is that he is a comparative rarity, and that the more zeal a man has for science the less regardful he is of self. Indeed, it has been maintained that in the virtues of unselfishness and truthfulness the man who has chosen the pursuit of science for his life-work noteworthily excels. No less an authority than Helmholtz, himself a man of the world as well as a great investigator, has spontaneously testified to this, speaking with enthusiasm of the scientific man's "Sittenstrenge" and his "Uneigennützige Begeisterung." Unfortunately, it is possible that this "Sittenstrenge" is exactly what our public men would consider an eccentricity, their short-sightedness leading them to mistake a surface freckle for a deep-seated defect.

Be all this as it may, however, it is important to urge on both sides the fact that the man of science and the man of affairs, whatever their respective frailties may be, have need of each other, and must therefore in the future strive to know each other better, and learn to cooperate more effectively in the interest of the State. To this end he who aims at State administration must seek to possess other qualities and other aptitudes than those of the mere party politician, so that, besides doing his own proper work well, he may be the better able to gauge the value of pure scientific work, and be the better fitted to sympathise with the ideals and aspirations of even the extremest of specialists. On the other hand, the specialist must aim a little more at width of outlook and knowledge of men and affairs, must seek to moderate his exaggerated estimate of the importance of his own little domain, and must try to see good in the labours of other specialists in fields far distant from his own, never forgetting that all fields are but perfectly fitted portions of a cosmic whole, and that, as the botanist and the astronomer in particular must come to know,

Thou canst not stir a flower
Without troubling a star.

It would be a neglected opportunity if we did not note in passing that the need for a good understanding between the devotee of statecraft and the student of science is only part of a much wider need. Men who aspire to be leaders in municipal affairs, in commerce, in trade, in the manufacturing industries, in agriculture, must all come to know how substantially dependent they are upon science, and how, indeed, in a very real way, they must become more and more scientific themselves in the conduct of their affairs. With them also the day is gone when rule-of-thumb is a sufficient guide. Even sound common sense, so great a standby in the past, is no longer enough: what is wanted is that glorified form of common sense known as scientific method. Practical men in every line of life are beginning to see this, though they may not use the term. In plain language, what it means is the employment, at every stage of a process or undertaking, of the means best suited to attain the desired end. And as a method it is always essentially the same, no matter how the desired end may vary—whether the latter be, as we in Cape Colony have seen it to be, the sanitation of a town, the tracking of a crime, the repression of a native rebellion, the fighting of an invading disease, or the capturing of a market for fruit or wool. In all of these there was the same need for collecting accurate data, using all previously acquired relevant knowledge, planning skilfully a course of procedure, selecting wisely the human agents necessary, and then prosecuting with steady persistency the plan resolved on.

I need hardly say, in conclusion, that all that the most enlightened State can do will never be fully effective without a continuance of that zeal and devotion on the part of the "private worker" which has been so conspicuous in the past history of science; and, fortunately, in the course of evolution man has become so constituted that a stoppage of the supply need not be feared. Many will still be found willing and eager to work for the work's sake, whether the State does its duty or the reverse, merely resting on the assurance that "Nature never did betray the heart that truly 'loved her.'"

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The special board for biology and geology has adjudged the Walsingham medal for 1910 to A. V. Hill, of Trinity College, for his essay entitled "The Heat Produced by Living Tissues, with Special Reference to Muscular Activity"; and a second Walsingham medal to J. C. F. Fryer, of Gonville and Caius College, for his essay entitled "The Structure and Formation of Aldabra and Neighbouring Islands—with Notes on their Flora and Fauna."

The Vice-Chancellor gives notice that the Walsingham medal for 1911 will be awarded for a monograph or essay giving evidences of original research on any botanical, geological, or zoological subject, zoology being understood to include animal morphology and physiology. The regulations for the medal are published in the *Ordinances*, p. 629. The competition is open to graduates of the University who at the time fixed for sending in the essays are not of standing to be created Master of Arts. The essays for the ensuing year are to be sent to the chairman of the special board for biology and geology (Prof. Langley, The Museums) not later than October 10, 1911.

It is proposed to confer the degree of science, *honoris causa*, upon Prof. George E. Hale, director of the Solar Observatory of the Carnegie Institution of Washington, Mount Wilson, California.

The Earl of Lytton will distribute the prizes and certificates at the Borough Polytechnic Institute on Monday next, December 19, at 8 p.m.

A Reuter message from Kimberley states that the De Beers Company has made a donation of 25,000*l.* towards the founding of a South African university.

We learn from *Science* that Yale University has received an anonymous gift of 3000*l.*, the interest of which is to be used as an emergency loan fund in the interest of instructors and assistant professors of the University; 6000*l.* of a fund of 10,000*l.* left to the University by the late Mr. J. Burnett Collins, of Fort Worth, Texas; 4000*l.* from Mr. Newton Barney, of Farmington, Conn., toward the fund for the professorship of education, and a like amount from the family of the late Mr. John H. Whittemore, of Naugatuck, as a memorial gift. From the same source we learn that the University of Vermont has just received 5000*l.* by the will of Mr. Lewis L. Coburn, a graduate of the class of 1859.

The annual meeting of the Mathematical Association is to be held on January 11, 1911, at the London Day Training College, Southampton Row, London, W.C. At 11 a.m. the president, Prof. H. H. Turner, F.R.S., will deliver his address, and this will be followed by a paper on the teaching of mechanics by Mr. G. Goodwill. The business meeting will begin at 2 p.m., and will be followed by the reading of papers. The Rev. Canon J. M. Wilson will deal with two fragments of geometrical treatises found in Worcester Cathedral library, and Mr. C. V. Durell will take as his subject the arithmetic syllabus in secondary schools. A discussion on the report of the committee on the teaching of algebra and trigonometry will take place, and an exhibition of scientific apparatus and books will be held.

In connection with the Winter School of Agriculture of the Essex Education Committee, a course of instruction on farm crops and livestock is to be conducted at the County Laboratories, Chelmsford, from January 9 to March 17 of next year. The aim of the winter school is to impart instruction in the cultivation of the soil, the growth of crops, and the rearing of stock, based upon a knowledge of the sciences on which the practice of agriculture depends. The instruction in chemistry and physics, botany and zoology, is accompanied by practical laboratory work. The lectures on agriculture and surveying are supplemented by field and other demonstrations, but no instruction is given in the actual processes of farm work, it being held that these must be learnt upon the farm itself. The school, in fact, is intended to supplement farm training, not to replace it. The instruction is free to students resident in the County of Essex. Applications to attend must be made to the principal on or before December 16, from whom further particulars and forms of application may be had.

It is proposed to organise in London next July a holiday course of lectures for the advancement of commercial studies. The object of the lectures is to familiarise the students—mainly commercial men and teachers of economics from Continental countries—with the history and practical working of English commerce and industry. The lectures are being arranged by the International Society for Promoting Commercial Education, which has already held similar annual courses in Milan, Mannheim, Havre, and Vienna. The society receives the patronage and financial support of many European Governments. The London course is to be held at the School of Economics, Clare Market, London, W.C., from July 24 to August 12 next. Arrangements are being made for securing the assistance as lecturers of the most eminent British authorities on economic and commercial subjects, and promises of help have been received already. An influential committee is in course of formation, and the names will shortly be announced. Persons interested in the subject are invited to communicate with the organising secretary for Great Britain, Mr. E. Cleveland-Stevens, School of Economics, Clare Market, London, W.C.

The Education Committee of the General Medical Council has been considering for a year the place in a medical student's career that the preliminary sciences should occupy, and it has been engaged also in discussing the framing a pattern scheme showing how the subjects required could be studied adequately and the necessary examination passed within the prescribed period. The report of the committee was submitted to the General Medical Council at its winter session held at the end of November. The Education Committee has come to the conclusion that the schools of the country generally are not at the present time in a position to take up the work of preparing students in the preliminary sciences, chemistry, physics, and biology, and that the student must study these subjects at a medical school or science institute. The committee further came to the conclusion that any attempt to fix a standard minimum curriculum would fail, and eventually recommended only the elimination of some of the more junior examinations—which are recognised as preliminary examinations in general education—and their replacement by tests of an intermediate character. After some discussion, in which it was clear that there was a large body of opinion against the committee's recommendations, the further consideration of the subject was postponed until the May session of the council next year.

At a meeting of the governing body of the Imperial College of Science and Technology, held on December 9, it was decided to invite Prof. Friedrich Czapek, of the University of Prague, to occupy the newly founded chair of plant physiology and pathology in the college, and to take immediate steps to afford the accommodation necessary for the important work of such a department. It is understood that, in furtherance of the aim of the Imperial College to apply science to industry, this chair has been founded to meet the needs for training young men to act as advisers in matters connected with agriculture at home and in the Empire abroad. Under existing conditions of agriculture it is everywhere recognised—notably by the large planting communities—that the advice of scientific experts has become absolutely necessary. There is, in fact, a demand considerably exceeding the supply for the services of trained scientific men to act in these capacities. Prof. Czapek enjoys a world-wide reputation as one of the leaders in plant physiology and pathology, and he has devoted special attention to the biochemical aspect of these subjects. It is precisely from this biochemical treatment that results of the highest importance for industry may be expected. We are informed that the college has every reason to expect that Prof. Czapek will accept the invitation. It is anticipated that the recognition of the importance of the business interests wrapped up in this work will justify the authorities of the college in looking beyond their immediate resources for the heavy initial expense required for building and suitably equipping such a department and for its subsequent maintenance.

At the annual Convocation of the Allahabad University, held on November 12 at the Muir Central College, the Vice-Chancellor, Mr. Richards, conferred the degrees and delivered an address. Great strides, he said, have been made with the project for providing the University with a habitation of its own. The plans prepared by Sir Swinton Jacob will be on view in the exhibition shortly to open in Allahabad. The plans include a senate hall with offices and committee rooms, a law college, and a university library. When the buildings are completed they will amply provide for all the needs of Allahabad University. All the money needed for carrying out the whole scheme has not yet been collected, but with Government

assistance and the donations promised and received some Rs. 7,00,000 can be counted on. Further donations are urgently needed. Later the Vice-Chancellor said the University may congratulate itself upon a windfall that has come to it during the year. A sum of more than Rs. 75,000 has been received from the Queen Victoria Memorial Fund as an endowment for founding readerships for research work. The institution of university chairs was recommended by the Universities' Commission of 1904 for this very purpose, and it has been a cherished hope for many years that Allahabad University might be able to do something for the promotion of research among its graduate members. Hitherto, for lack of funds, nothing could be done. Now, however, a beginning can be made, and though it must be in a modest way at first, it inaugurates a new and important era in development; and as time goes on it will attract other benefactions, until the University has at length sufficient funds for research in all the directions of university study.

THE report on the work of the Department of Technology of the City and Guilds of London Institute for the session 1909–10 is now available. At the recent examinations 24,508 candidates were presented in technology from 418 centres in the United Kingdom, and of these 14,105 passed. By including the candidates from India and the colonies, and those for the teachers' certificates in manual training and domestic economy, the total number of examinees was 26,878. These figures show an increase on those of any previous year. In order to secure the expert advice of trade societies and professional bodies in the conduct of the department's educational work, the institute has arranged for the formation of advisory committees, consisting of persons interested in, and with a knowledge of, the technical details of different industries. The functions of each committee are to suggest improvements in the syllabuses of instruction, to recommend for appointment new examiners, and generally to advise on any matter connected with the course of instruction which may be referred to them by the institute. Reference has been made in former reports to the two main causes which impede progress in the technical instruction of artisans, and prevent the results of the teaching, now so liberally provided by local authorities, from being as satisfactory as might be desired. These causes are emphasised in the special reports of several of the institute's examiners. They are, first, the difficulty of finding competent teachers, and, secondly, the unduly large proportion of artisan students who enter technical classes without the preliminary knowledge necessary to take full advantage of the instruction they receive. While local authorities accept readily the advice and assistance of the department in their selection of teachers, and a higher standard of qualification is now more generally required, further improvement in this direction must be looked for if the money expended on technical instruction is to produce its best results. There can be no doubt that the teaching of technology has greatly improved during the past few years, but it must be noted that the examiners have still to direct attention repeatedly to the insufficient preliminary knowledge that some candidates possess.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, November 23.—Prof. W. W. Watts, F.R.S., president, in the chair.—Dr. W. F. **Hume**: The effects of secular oscillation in Egypt during the Eocene and Cretaceous periods. There is evidence of the gradual advance of the Cretaceous sea from north or north-east over Egypt during Upper Cretaceous times. Four stages in this advance are indicated by the distribution of the Cretaceous deposits. The four phases are:—(*a*) A north Egyptian type, in which the Nubian Sandstone entirely underlies fossiliferous beds of Cenomanian age. This extends across Egypt from Sinai to Baharia Oasis. (*b*) A Wadi-Qena type, developed near the head of the valley of that name, characterised by the alternation of Nubian Sandstone with fossiliferous Cretaceous beds. (*c*) A central Egyptian or Hammama type, in which the Nubian Sandstone forms the greater portion of the Cretaceous series, only the Danian and Campanian beds being fossiliferous limestones or shales. The Campanian beds are characterised by the presence of phosphatic fish-beds. (*d*) A south Egyptian type has resemblances to the central Egyptian, but in the Campanian the phosphatic beds are inconspicuous. As regards the transition from the Cretaceous to the Eocene, the existence of two types of strata at the base of the Eocene is noted: the first, the Luxor type, being fossiliferous, and developed in the Western Desert; the second, or Qena type, being unfossiliferous, and composed of white limestone similar to the Danian white limestone below them, but structurally different. These variations may be due to fold-effects produced while the land was gaining on the sea at the beginning of Eocene times, the Qena limestones being remade Cretaceous material. Whereas in southern Egypt Lower Eocene strata directly overlie the Danian strata, in northern Egypt unconformities exist between the Middle Eocene and the Cretaceous beds. The palæontological differences between the Cretaceous and the Eocene are recorded, the principal feature being the sudden incoming of the foraminifera Nummulites and Operculina. The distribution, zonation, and variation of the Eocene series are considered. The apparent uniformity of the fossiliferous Lower Eocene strata wherever developed is noted. The lack of uniformity in the Middle Eocene strata. The nature of the Eocene beds between Baharia Oasis and the depressions of Moela and the Fayum are described, zoned, and compared with the Middle Eocene in other parts of Egypt. The influence of the gain of land over sea is traced through the Upper Moqattam beds. The Cretaceous period in Egypt is marked by the gradual gain of sea over land; during the Eocene land appears to have been steadily gaining on the sea, probably accompanied by gentle fold-movements, which account for the minor differences in the nature of the Eocene deposits.—A. R. **Horwood**: The origin of the British Trias. During the Triassic period in Britain, deposition, it is maintained, was brought about solely by the action of water, and the British Trias is a delta-system, for during Carboniferous, Permian, and Triassic times deposition was mainly in the same area. There is a gradation from the Bunter to the Rhætic. The Bunter is known to be of fluviatile origin, and there is a continuity from Lower to Upper Trias, with an unconformity due to the new mode of formation and change in sedimentation. Oscillation and overlapping are admittedly due to aqueous agency. The Triassic outcrop and the delta-area of the river Mississippi are closely similar. Coloration is original, from below upwards, and not coincident with bedding. The thickness of the Bunter is an argument for a subsiding area. The ferruginous types in the Carboniferous, Permian, and Trias are alike due to delta conditions. The Trias is horizontal now, as originally, away from any ancient hills which it covers. It is only the skerries that are rippled. Screes occur mainly to the south-west of submerged hills. Sandstones thin out eastward, marls westward, and the skerries are on the hills. Rock-salt and gypsum are also horizontal and continuous in a linear direction. The Keuper gradually merges into the Rhætic phase, and the latter into the Lias. Since the Bunter sediments came from the north-west into the Midlands, so probably did the Upper Trias. Local metamorphic and volcanic rocks may have provided some of the heavier minerals, but, as a whole, their source was more distant. The flora and fauna can be grouped in provinces around the delta-head of the Trias. These considerations point to an aqueous mode of sedimentation in a moist and equable climate.

Physical Society, November 25.—Prof. H. L. Callendar F.R.S., president, in the chair.—Dr. A. **Russell**: The electric stress at which ionisation begins in air. Prof. J. B. Whitehead has published the values of the electric stress at which ionisation begins in air. His electrodes consisted of a metal tube and a cylindrical wire coaxial with it. Alternating pressures were employed, and the inner wires had diameters from 0·089 to 0·475 cm. If a be the radius of the inner wire, the expression $32+13{\cdot}4/\sqrt{a}$ gives all Whitehead's experimental results for the maximum electric stress in kilovolts per centimetre with a maximum inaccuracy of less than 1 per cent. Experiments show that the electric stress at which ionisation occurs is independent of the metals used for the electrodes

and of the inner radius of the outer tube. It depends on the radius of the inner wire. Steinmetz's experimental results on the sparking distances between parallel rods are in substantial agreement with Whitehead's figures. An empirical formula based on experimental results published by Kowalski and Rappel is given for the sparking voltages between equal spherical electrodes. The electric stress at the moment of discharge has a minimum value when the distance between the electrodes is a certain function of their radius. Great stress is laid on the currents of electrified air which stream round the electrodes before the discharge takes place. These currents often modify the values obtained for the disruptive stress at the moment of discharge. The similarity between the formulæ for the temperature gradient at the surface of a hot wire cooling in air and the empirical formula for the potential gradient at the surface of an electrified wire when ionisation is taking place at its surface is pointed out.—Prof. R. J. **Strutt**: The afterglow of electric discharge. When the electric discharge has passed at low pressure through certain gaseous mixtures, a luminosity survives for some seconds after the discharge has been turned off. An improved method of experimenting on the phenomena was introduced by Dewar. A powerful air-pump is used to draw a regulated current of gas through the vacuum tube. A continuous removal of the gas from the region of discharge is effected, and the afterglow which it emits, in passing through another vessel on its way to the pump, can be examined continuously and at leisure. There has been difference of opinion as to whether pure oxygen shows a glow or not. The glow, if any, is certainly exceedingly faint. With air a bright yellow glow is obtained, which is improved by enriching the air with oxygen. Pure nitrogen gives no glow whatever. Previous experimenters have connected the glow with ozone, though without expressing definite views as to what part ozone played. The evidence for this has been that the glow is only obtained where oxygen is present, and that it is destroyed by heat. Additional evidence has been obtained. (1) The glow cannot survive passage through a tube cooled in liquid air. This is regarded as due to condensation of ozone. (2) It is destroyed by passage over oxides of copper, manganese, and silver. Ozone is known to be destroyed by these substances. (3) While the glowing gas oxidises bright silver, the gas current beyond the point at which the glow has died out does not do so. Disappearance of the glow is simultaneous with disappearance of ozone from the gas. The glow involves consumption of ozone. It is natural to regard it as a flame of low temperature, arising from the oxidation of some other body by ozone. Experiments were made to determine the nature of this other body. A current of ozone from a vacuum tube fed with oxygen was allowed to mix with any other gas which it was desired to test on its way to the pump. Nitrogen or ordinary air added to the ozone gave no effect, but air which had been through an independent discharge, and had been deprived of its original glow by silver oxide, was found to glow again on mixing with ozone. Some body is produced in air by the discharge the oxidation of which is responsible for the glow. This body is nitric oxide. On leading a current of this gas into the ozone stream a brilliant glow was obtained of the characteristic yellow colour. This glow can be produced in the form of a pointed flame, with dark inner cone. The glow is not associated with a sensible rise of temperature. Condensing the ozone with liquid air, allowing it to re-evaporate, and admitting nitric oxide to it, a yellow flash can be obtained long after the electric discharge is over. The glow is purely chemical in its origin. Ozone from the Siemens tube used at atmospheric pressure seems incapable of yielding the glow when mixed with nitric oxide. This may be due to the low percentage of ozone present. The main conclusion is that the ordinary yellow afterglow is due to oxidation of nitric oxide by ozone.—L. F. **Richardson**: The approximate solution of various boundary problems by surface integration combined with freehand graphs.

Zoological Society, November 29.—Dr. H. Woodward F.R.S., vice-president, in the chair.—Dr. H. B. **Fantham** and Dr. H. Hammond **Smith**: A possible cause of pneumo-enteritis in the red grouse (*Lagopus scoticus*). The authors recorded that in grouse-chicks dying of coccidiosis, many of which showed symptoms of pneumonia, they found coccidian oöcysts in the bronchioles, bronchi, and trachea. The coccidian cysts in the bronchioles were probably capable of setting up sufficient irritation to account for the pneumonic symptoms. These observations were interesting as showing that the much criticised views of Klein, Tegetmeier, and others on "pneumo-enteritic" as a cause of mortality in grouse may have some foundation in fact.—Dr. J. F. **Gemmill**: The development of *Solaster endeca*, Forbes. The author described the ovaries and ova and the processes of spawning, fertilisation, segmentation, and gastrulation, and then dealt with the characters of the free-swimming larvæ and the changes related to the metamorphosis. He discussed the development of the internal cavities and of the skeleton, and described the methods he had employed in obtaining and rearing the larvæ. The memoir, in addition to details of adult anatomy, contained a description of various points in development.—F. E. **Beddard**: The alimentary tract of certain birds, and on the mesenteric relations of the intestinal loops. Notes the author had accumulated relative to the viscera of birds which had died in the society's gardens. The paper dealt more particularly with species that had not been carefully studied from the point of view of the convolutions of the intestine, and attention was directed to a considerable series of birds.—Prof. A. **Cabrera**: The specimens of spotted hyænas in the British Museum (Natural History). Three apparently new forms were described.

Linnean Society, December 1.—Dr. D. H. Scott, F.R.S., president, in the chair.—Captain C. F. **Meek**: The spermatogenesis of *Stenobothrus viridulus*, with special reference to the heterotropic chromosome as a sex determinant in grasshoppers.

Mathematical Society, December 8.—Dr. H. F. Baker, president, in the chair.—G. H. **Hardy**: Properties of logarithmico-exponential functions.—G. H. **Hardy**: Some results concerning the increase of functions defined by an algebraic differential equation of the first order.—A. A. **Robb**: Optical geometry of motion.—T. C. **Lewis**: Note on the Pellian equation.—G. B. **Mathews**: The arithmetical theory of binary cubic forms.—Dr. W. H. **Young**: The integration of Fourier's series.—Dr. W. H. **Young**: The theory of the application of expansions to definite integrals.

Royal Astronomical Society, December 9.—Sir David Gill, K.C.B., president, in the chair.—A. C. D. **Crommelin**: Note on Mr. Innes's paper on the mean or perihelion distances of comets.—A. Stanley **Williams**: The equatorial current of Jupiter in 1880. The author concluded from observations of eight spots that the rotation period of the equatorial current in 1880–1 was nearly 20 sec. shorter than during the years 1888–1908, amounting to a difference in velocity of about 15 miles an hour.—A. A. **Rambaut**: Observations of Halley's comet, Daniel's comet (1909*e*), and comet 1910*e*, made at the Radcliffe Observatory, Oxford.—A. A. **Rambaut**: Observations of stars occulted by the moon during the eclipse of 1910 November 16. A photograph of the eclipsed moon and trails of stars was shown, the telescope having been adjusted to the moon's motion during the eclipse.—C. V. L. **Charlier**: Multiple solutions in the determination of orbits from three observations. The author showed that in certain regions more than one solution could be obtained from the observations, while in others only one was possible; in consequence of this, much difficulty was somtimes found in obtaining the true orbit, as was the case with comet 1910*a*.—H. H. **Turner**: The accuracy of the positions of the star images in the "Harvard Sky." By the latter term was intended the Harvard series of fifty-five plates, forming a photographic map of the heavens on a scale about one-eleventh that of the Astrographic Catalogue. Formulæ were given for computing the optical distortion, varying as the cube of the distance from the centre of the plates, and also for the differential refraction.—S. A. **Saunder**: The determination of selenographic positions, and the measurement of lunar photo-

graphs. Fifth paper: Results of the measurement of two Yerkes negatives. The negatives, taken by Prof. Ritchey, were extremely fine, but their dates—given as 1901 August 3 and November 21—were uncertain. The result of the author's reduction of the measures of the plates enabled him to show that they were actually taken on September 3 and November 20. The measures appeared to show that points on the moon greatly above or below the mean surface should be rejected, owing to their being shifted in opposite directions by libration. A diagram was drawn to exhibit the close agreement between points independently measured on photographs by Prof. Franz and Mr. Saunder compared with the considerable divergence in the positions of the same points as determined by Lohrmann and Mädler. The actual measures had been made on the negatives by Mr. Hardcastle.

PARIS.

Academy of Sciences, December 3.—M. Émile Picard in the chair.—G. **Lippmann**: Two pieces of metal lightly touching do not, in general, form an electrical contact when the difference of potential is small. Two forms of contact are described in which no pressure is necessary. In one of these a strip of paper moistened with a solution of an electrolyte (calcium chloride) is employed; the second consists of two amalgamated silver wires.—A. **Gautier**: Concerning the invention of porous filtering candles. The author points out that he described the manufacture and use of porous porcelain filters two years before Ch. Chamberland.—A. **Laveran** and A. **Pettit**: A new hæmogregarian of *Damonia subtrijuga*.—M. **Gouy**: The potential of the discharge in a magnetic field. —W. **Kilian** and M. **Gignoux**: The levels of the pebble beds and terraces in the neighbourhood of Saint-Rambert-d'Albon (Drôme) and of Beaurepaire (Isère).—M. Lecornu was elected a member in the section of mechanics in the place of the late M. Maurice Levy.—G. D. **Boerlage**: An attempt at "*vol à vortex.*" Attention is directed to the effect of the thickness of the front edge of the wing in birds, and the author suggests that an attempt might be made to realise these conditions in aëroplanes.—M. **Lambert**: A form of the equations of motion of a small planet.—M. **Borrelly**: Observations of the new Cerulli comet made at the Observatory of Marseilles with the comet finder. Data are given for November 10, 12, 14, and 16.—M. **Coggia**: Observations of the Faye comet (1910*e*, Cerulli, November 9) made at the Observatory of Marseilles with the Eichens equatorial of 26-cm. aperture. Positions are given for November 12 and 16.—P. E. **Gau**: The integration, by the method of M. Darboux, of any partial differential equation of the second order.—T. **Lalesco**: The poles of resolving nuclei.—Henri **Villat**: The movements of a fluid round an obstacle of given form. —Marcel **Chopin**: The absolute measurement of currents of great intensity. A description of a modified tangent galvanometer capable of measuring currents up to 1000 amperes.—M. **Tian**: The nature of the decomposition of hydrogen peroxide solutions produced by light. It has been shown that the decomposition of hydrogen peroxide by heat is a bimolecular reaction, whilst the decomposition by catalysis in presence of colloidal platinum, diastase, &c., is a unimolecular reaction. An experimental study of the decomposition produced by ultra-violet light shows that the reaction is unimolecular, and hence is not analogous to the action of heat, but rather resembles catalytic decomposition.—Paul **Jégou**: The reception of the Hertzian time signal from the Eiffel Tower. The apparatus described and illustrated works with Leclanche cells instead of secondary batteries, and is simplified in other directions.—L. **Décombe**: The mechanical interpretation of the principle of Carnot and Clausius. The case of a compensated transformation.—F. **Charron**: The modifications produced by the air layer in friction and sliding between solid bodies.—Br. **Glatzel**: New experiments in stimulation by shocks in wireless telegraphy. It is well known that by interposing very short sparks into the primary circuit of a Hertzian wave excitor the vibrations in this circuit are effectually deadened. The author passes the sparks through a tube containing hydrogen between nickel electrodes. Reproductions of photographs are given showing the complete damping effect obtained. —R. **Marcelin**: The mechanics of irreversible phenomena.—A. **Besson** and L. **Fournier**: By passing a rapid current of hydrogen bromide over amorphous silicon at a red heat a liquid is obtained which, on submitting to fractional distillation, gives as the main product of the reaction silicon tetrabromide; small quantities of SiH_2Br_2 are also obtained, and also a liquid which appears to be a mixture of this with SiH_3Br. Details are also given of a rapid method of preparing a crude silicon suitable for the reaction. By the action of the silent discharge upon the vapours of the silicobromoform four substances were identified, $SiBr_4$, Si_2Br_6, Si_3Br_8, and Si_4Br_{10}, the silicon analogues of tetrabromomethane, octobrompropane, and decabrombutane.—E. A. **Salmon**: A method for producing a reaction between two bodies in the electric arc.—L. **Tchougaeff** and W. **Fomin**: The addition of hydrogen to the isomeric thujenes and sabinene. The application of the Sabatier and Senderens reactions having been shown to be too energetic in the case of these two hydrocarbons, the addition of two atoms of hydrogen to each molecule was effected by the catalytic action of platinum black, the hydrogen being used under a pressure of 25 to 50 atmospheres. The physical and chemical properties of the resulting hydrocarbons are given.—Georges **Denigès**: A new reaction of morphine. The reagent proposed is a mixture of ammonia, hydrogen peroxide, and copper sulphate in aqueous solution. A red colour is produced if the concentration of the morphine is above 0·03 gram per litre. This reaction gives negative results with codeine, thebaine, papaverine, narceine, and narcotine.—A. **Verneuil**: The nature of the oxides causing the coloration of the Oriental sapphire. Careful analyses of sapphires from different sources (Montana, Burmah, and Australia) showed the invariable constituents to be oxide of iron and oxide of titanium. The latter oxide was not detected in the earlier analyses by other workers. No chromium was found in the two sapphires examined for this element, and the author concludes that chromium is not essential to the production of the characteristic colour. The conclusion that the colour is due to the oxides of titanium and iron alone is confirmed by the synthesis of the gem by fusion previously described.—Henri **Coupin**: The influence of various volatile substances on the higher plants.—L. **Moreau** and E. **Vinet**: Insecticide treatments in viticulture.—Ed. **Griffon**: The influence of the tarring of roads on the adjacent vegetation. The author comes to the conclusion that no injurious effect to vegetation can be proved to have been caused by the tarring of roads. Laboratory results cannot be regarded as conclusive on this point, which can only be settled by actual practice in the open air.—MM. **Melchissédec** and **Frossard**: Muscular fatigue in singing.—M. **Doyon**: The formation of antirhombine in the liver previously frozen at a very low temperature.—G. **Linossier**: The influence of iron on the formation of the spores of *Aspergillus niger*. It has been shown by previous workers that if iron be omitted from the culture solutions of *Aspergillus niger* spores are not formed. The author has extracted the black pigment from the spores of this mould, and shows that it possesses properties resembling the hæmatin of the blood, and contains iron as an essential constituent. This furnishes a full explanation of the impossibility of producing spores in the absence of iron.—Gabriel **Bertrand** and Arthur **Compton**: The influence of temperature on the activity of cellase. Cellase from sweet almonds has a maximum activity at a temperature of 46° C. This is independent of the duration of heating, and is a specific value of great interest.—M. **Lemoine**: The presence of deposits of cholesterol in the coats of sclero-ætheromatous arteries.—Ch. **Vélain** and Albert **Michel-Lévy**: The primary strata of the south of the Vosges.—MM. **Bernard** and **Mougin**: The stratification of the *névé* and of the ice in the upper regions of the collecting areas of glaciers.—Ph. **Glangeaud**: The glacial phenomena in the mountains of Forez.—Paul **Bertrand**: General characters of the stipes of *Asterochlaena laxa*.—M. **Martel**: The removal of obstruction in water-bearing fissures.—P. **Mercanton**: The magnetic condition of the diabases of Isfjord at Spitsbergen.—Louis **Gentil**: The lower Mlouya (eastern Morocco).

NEW SOUTH WALES.

Linnean Society, September 28.—Mr. C. Hedley, president, in the chair.—C. T. **Musson** and W. M. **Carne**: The adventitious roots of *Melaleuca linariifolia*, Sm.—R. J. **Tillyard**: Some experiments with dragon-fly larvæ. This paper embodies the results of experiments carried out with the object of showing:—(1) That dragon-fly larvæ of certain kinds live longer than one year. An unknown Libellulid larva taken at Heathcote on October 10, 1908, and more than half-grown then, has lived in an aquarium to the present date. It now appears full-fed, and may be expected to emerge this season. Its age, from the egg, must be more than two and a half years. (2) That certain dragon-fly larvæ can resist severe and prolonged drought. Eight larvæ of *Synthemis eustalacta*, Burm., were placed in a shallow-water aquarium over sand; no food given from December 25, 1909, and water allowed to evaporate. The aquarium was dry on February 2, and the larvæ were kept alive, hidden in the sand, until May 29, a period of nearly four months. The larvæ were then returned to water and fed up. Seven are still alive, and may be expected to emerge this season.—T. Harvey **Johnston** and Dr. J. Burton **Cleland**: The Hæmatozoa of Australian Reptilia. No. 1. A list of Australian reptiles from which Hæmatozoa have been recorded is given, and three species of Haemogregarina (Karyolysus) are described as new.

October 26.—Mr. C. Hedley, president, in the chair.—T. **Iredale**: An additional note on the birds of Lord Howe and Norfolk Islands. The opportunity of inspecting the Watling drawings in the British Museum prompted the author to investigate the authenticity of the early chronicles relating to some of the birds of Norfolk and Lord Howe Islands, now extinct, or the identity of which has never been settled satisfactorily. From the consideration of the historical evidence available, the author concludes that the extinct white gallinule (*Notornis alba*) was restricted to Lord Howe Island; that the "Norfolk Island petrel" of Latham is probably *Puffinus griseus*, Gm., which still breeds about the typical locality, and not *P. chlororhynchus*, Less., as supposed by the late Dr. Sharpe; and that drawing No. 282, regarded by Dr. Sharpe as representing *P. tenuirostris*, Temm., is undoubtedly a figure of the Œstrelata still breeding, or which apparently used to breed, on Norfolk Island, which must bear the name *Œstrelata phillipi*, Gray, and which is different from *Œ. neglecta*, Schl. Some omissions are rectified, and observations supplementary to those of Mr. Hull (Proceedings, 1909, p. 636) are given.—A. F. Basset **Hull**: Further notes on the birds of Lord Howe and Norfolk Islands, with the description of a new species of petrel. The author endeavours to dispel the uncertainty enshrouding the identification of the petrels of Norfolk Island. Captain Hunter's "bird of providence" remains a mystery, as visits to Mount Pitt in November, and in the succeeding year in August, offered no signs of birds or burrows, a condition of things possibly due to the extermination of the old-time colony, or its removal to more secure breeding grounds. The "Big Hill mutton-bird" of Lord Howe Island, which breeds upon Mount Gower, is shown to be markedly different from *Œstrelata neglecta*, Schlg., and is described as new.—J. H. **Maiden** and E. **Betche**: Notes from the Botanic Gardens, Sydney. No. 16.—A. M. **Lea**: Australian and Tasmanian Pselaphidæ (Coleoptera).

PROBLEMS OF CROWN COLONY ADMINISTRATION.

The Broad Stone of Empire. Problems of Crown Colony Administration, with Records of Personal Experience. By Sir Charles Bruce, G.C.M.G. Vol. i., pp. xxxiv+511+2 maps. Vol ii., pp. viii+555+4 maps. (London: Macmillan and Co., Ltd., 1910.) Price 30*s.* net, two vols.

According to the description on the title-page, this book purports to discuss problems of Crown Colony administration, and to contain, as a subsidiary matter, records of personal experience. The first volume carries out, on the whole, the promise of the title-page, but the second is in effect a record of Sir Charles Bruce's *acta et verba* during the thirty-six years of his faithful and efficient public service in Ceylon, British Guiana, the West Indies, and Mauritius; and the discussion of problems of Crown Colony administration forms little more than a setting for the account of his experiences, and of the recognition which his valuable services deservedly received, from time to time, at the hands of his official superiors. Lengthy despatches and memoranda, much of which might with advantage have been omitted and the rest severely condensed, encumber the pages of the book, and were it not that it is provided with an excellent index, its undoubted value as a work of reference for students of colonial administration would be gravely compromised.

The book, which extends to some 1100 pages, after discussing the resources of the Crown Colonies, and British policy in connection with them, under the heads of national, colonial, and imperial, treats of the Colonial Office and the Colonial Governor; and there are chapters on law, labour, race, health, education, religion, agriculture, forestry, commerce, finance, transport, meteorology, imperial communications, fiscal system, expansion, defence, and the Crown. There are seven appendices, of which two, namely Mr. Edward Manson's memorandum on systems of law obtaining in the Crown Colonies, and a memorandum on measures to be carried out for prevention of malarial fever in Mauritius, are of special interest to students of Crown Colony administration, and, as already mentioned, there is an excellent index.

Within the limits of a short review it is not possible to discuss more than one or two of the subjects with which the author deals; it must suffice to indicate the rest, and to say that (apart from a certain discursiveness and from the other drawbacks to which we have felt bound to direct attention), the student of problems of Crown Colony administration will find much in the various chapters to reward his industry and to satisfy his curiosity. To the readers of NATURE the chapters on agriculture and on forestry, the chapter on meteorology, and the two chapters on health, will probably be of the greater interest than the others. The description of the work of the Imperial Department of Agriculture in the West Indies, which has done so much during the last ten years towards helping to restore the prosperity of the West Indian Colonies is interesting; the sketch of the progress of agriculture in Ceylon is instructive; and the chapter on forestry shows of what vital importance are conservation of forests and reafforestation, and how much remains to be done in that regard. The chapter on meteorology is practically confined to an account, interesting so far as it goes, of the work done under the auspices of Dr. Meldrum at the Mauritius Observatory. The most interesting chapters of all are the chapters on "Health." Only those who have lived in unhealthy climates can fully realise of what vital importance it is to the progress of a community that effectual means should be found for combating the diseases which in so many of the most fertile of the British Dominions beyond the seas have so hampered what Sir Charles Bruce well calls the "agencies of beneficial occupation"—industry, commerce, military and naval defence, and good government—and how dependent those agencies are on the preservation of health against tropical diseases. In this field of later years science has rendered yeoman service to the State, and to the pioneers of civilisation and progress in the tropical and subtropical dependencies of the Crown, and, indeed, throughout the world. Malaria is no longer an elusive bogey; yellow fever has lost much of its terrors; even plague and cholera, in communities which have been brought to understand the value and necessity of the precautionary measures prescribed by science, can be successfully combated and brought under control.

Yellow fever has been practically banished from its hot-bed, Havana. The isthmus of Panama, which is credited with having killed one workman for every sleeper of the Panama Railway, is no longer a particularly risky place of residence. Our garrison and fleet at Malta no longer suffer from Malta fever. Ismailia, formerly a hot-bed of malaria, has been rendered perfectly healthy. The dreaded sleeping sickness, although no absolute cure has yet been found for it, has, in Uganda, at all events, been brought under control. It is unnecessary to multiply instances. And apart from what has been done in the matter of prevention and cure of diseases which affect mankind, the labours of the bacteriologist, protozoologist, entomologist, and helminthologist have contributed in no small degree to the progress and prosperity of the tropical and subtropical colonies. This has been done by discovering and tracing the life-history and development of the lower forms of life which are the cause of many of the fatal diseases to which stock, especially in tropical and subtropical lands, are subject, in tracing out the means by which they are communicated, and the life-history of their transmitters, or intermediate hosts, in devising preventive measures, and preparing vaccines or serums, and searching for and discovering drugs which act as prophylactics or as cures.

The two branches of scientific inquiry—as regards human disease, and as regards diseases of animals—are, indeed, to a great extent interdependent. The discovery of the trypanosome of nagana in cattle and of its transmission by *Glossina morsitans* may be said to have pointed to the discovery of the transmission

of the trypanosome of sleeping sickness to man by *G. palpalis*. The discovery that the trypanosome of sleeping sickness persists and grows in *G. palpalis* is akin to the discovery of the development of the malaria parasite in the anopheles. The discovery of the transmission of the piroplasma of Texas fever, of East Coast fever, and of "biliary fever" in stock, by means of ticks, pointed the way to the discovery of the transmission by ticks to man of the spirillum of relapsing fever. There may be some reason to hope that the exhaustive investigation of the causes of grouse disease which is now in progress may possibly lead to a better understanding of the causes of appendicitis in the human subject. Many similar instances might be mentioned. But this is not the place for an essay on the recent history of bacteriology.

Much yet remains to be done. The cause of and specific remedy for blackwater fever, that scourge of tropical Africa, is still to seek. An effectual remedy for sleeping sickness still makes itself desired. Leprosy still baffles the investigator. No cure for bilharzia has yet been found. Prophylaxis for horse-sickness amongst horses, hitherto baffled by hæmolysis, has still to be discovered. (For mules a fairly satisfactory prophylactic has been found.) Piroplasma, for which, in dogs, a specific cure has been discovered, in horses and cattle still presents an unsolved problem.

But the future is full of hope. Such great strides in advance have been made during the last few years that no difficulty seems, to the investigator, to be insuperable. Perhaps the most interesting of the later developments is the discovery of a series of facts which point to the probability of the terribly fatal fever, hitherto called malaria, on the west coast of Africa, being really a form of yellow fever. This matter is now, or is shortly, about to be brought under exhaustive investigation; and should the probability turn out to be a reality, the adoption on the Coast of precautions similar to those which have proved so successful on the isthmus of Panama should render the Gold Coast as healthy as Barbados. Small wonder that an influentially signed address has been sent to the Memorial Committee, suggesting that the name of our beloved Sovereign, the late King Edward the Seventh, cannot be better commemorated than by a liberal endowment of the schools of tropical medicine, which in these later years have done so much for the promotion of bacteriological research and the prophylaxis and cure of tropical diseases, both in the United Kingdom and in the British Dominions beyond the seas.

THE MICROSCOPE AS AN OPTICAL INSTRUMENT.

Microscopy. The Construction, Theory, and Use of the Microscope. By E. J. Spitta. Second edition. Pp. xxii+502+xvi plates. (London: J. Murray, 1910.) Price 12*s.* 6*d.* net.

THE views expressed in the previous notice of this work which appeared in NATURE (February 6, 1908) would appear to have been amply borne out in the welcome accorded to it by the public, since a second edition has already become necessary. Continued use of the volume as a book of reference has thoroughly confirmed the original opinion formed as to its value for the purposes of the practical microscopist. While much more limited in scope than the classical work of Carpenter and Dallinger, being restricted to the consideration of the microscope as an optical instrument, it has from this point of view already largely superseded the older work. Dr. Spitta is fortunate, too, in having obtained, in dealing with the more theoretical portions of the subject, the assistance of Mr. Conrady, whose excellent mathematical knowledge has helped to keep the book free from any of the remarkable theories in connection with the microscope which have been put forward in recent years, and have even found acceptance from some skilled practical microscopists.

One of the features of the first edition of the book was that it was well up-to-date in the account given of present-day microscopes and microscope construction and accessories. There was thus the less necessity for changes in a new edition appearing after such a comparatively short interval. Nevertheless, besides the one or two more important additions of which mention is made below, advantage has been taken of the opportunity offered to include some of the most recent work. Old illustrations of microscopes by prominent makers have been replaced by others of the newest types, and descriptions of novel accessory apparatus are given. We note that the name of the Spencer Lens Co., of Buffalo, N.Y., now appears for the first time, their stand for critical work being fully illustrated, and attention is directed to their one-sixth objective with specially long working distance (1 mm.). A new sixth by Watson and Sons, and one by Reichert, with extra long working distance, are also mentioned. Illustrations of newer models by Zeiss, Beck, and Watson take the place of those previously given, and some forms of museum microscopes, with mechanical contrivances for bringing a series of slides successively into the field of view, are now described.

Among additional accessory apparatus may be mentioned the simple form of apertometer devised by Mr. F. J. Cheshire; new illuminators, especially the convenient miniature arc lamp by Leitz; Mr. J. W. Gordon's lamp with glass-rod light collector, and Mr. J. E. Barnard's mercury-vapour lamp for microscopists—very convenient, with screens, for obtaining monochromatic light; a new auxiliary stage by Watson and Sons; forms of gauges for measuring the thicknesses of cover glasses and slips; measuring oculars or eyepiece micrometers; and a simplified apparatus and method of preparing metallurgical specimens for microscopical examination. The last would appear to be outside the limits of the work, which does not deal with the extensive subject of the preparation of specimens. We have noted also a number of changes in the text, whether by way of omission of unnecessary matter, or additions to render explanations clearer. It is interesting that Dr. Spitta appears finally to have come to the conclusion, with reference to the "black dot" and "white dot" effects in pleurosigma, that "the better the combination (objective) the better the rendering of the black dot effect, no matter the appearance, within reasonable limits, of the white one."

We would remark also that in his chapter on the "Theories of Microscopical Vision," Mr. Conrady adds a few paragraphs giving a short account of the connection between N.A. and the vision of minute objects of dimensions below the resolution limit, whether self-luminous or opaque.

The more important additions are those which deal with the extension of dark ground illumination to high powers, and the description of Siedentopf's apparatus for viewing ultra-microscopic particles. Dark ground illumination at high powers is obtained by the use of a condenser or illuminator of special type, which brings the light, usually with the aid of side reflection, to a focus on the specimen at a very oblique angle. Types of such condensers by Leitz, Zeiss, and Beck are described, and the method will no doubt be of value to the bacteriologist.

The Siedentopf method for illuminating ultra-microscopic particles is well known. The subject perhaps lies outside the range of the ordinary microscopist.

Finally, it may be mentioned that the already excellent series of photomicrographs has been extended by the introduction of four or five interesting photographs of amphipleura. Unfortunately, in the copy we have seen, the printers have made the mistake of printing the descriptive text on the wrong side of the thin paper separating the plates, with the result of making it somewhat difficult to read.

GEOMETRY OF SURFACES.

A Treatise on the Geometry of Surfaces. By A. B. Basset, F.R.S. Pp. xvi+291. (Cambridge: Deighton Bell and Co.; London: G. Bell and Sons, 1910.) Price 10s. 6d.

ACCORDING to his preface, Mr. Basset intends this book to supply a want in English works on solid geometry, namely, an adequate account of surfaces other than quadrics, the existing gap being due to the fact that Salmon's "Geometry of Three Dimensions" is now out of print.

The greater part of the book seems to be devoted to a detailed examination of the various types of singularities which can occur in surfaces of order not higher than the fourth; such a lengthy investigation cannot be properly criticised except at the cost of great labour. But, for reasons given below, it is doubtful if the method adopted for resolving higher singularities is really sufficient to do all that is claimed by the author.

It is not altogether clear, either, for what class of readers the book is intended; the greater part of the results will interest none but specialists in geometry. And one may imagine that such specialists might be tempted to ask why the analytical machinery is developed purely from metrical definitions, when the properties to be established are mainly projective (or descriptive) in character. Thus, *reciprocation* seems always to refer to a *sphere,* and *homogeneous coordinates* are defined (§3) only as *perpendiculars* on the faces of a tetrahedron. It is not quite easy to see how Mr. Basset would justify the use of coordinates such as $x+iy$, $x-iy$, on the last definition.

However, there is probably a wider circle of readers, not claiming to be geometrical specialists, who would take an intelligent interest in an account of the properties of cubic and quartic curves and surfaces, and particularly in results which are related to work in other subjects. Such readers might also find it useful to have information as to various models available for the illustration of the shapes of the figures; doubtless the expert geometer disdains these mental crutches, and relies on his powers of intuition. But those of us who confess to finding it difficult to visualise surfaces from their equations, are able to point to geometrical experts who have been led to unexpected results by the consideration of models; one need only mention Kummer's model of the surface of centres of an ellipsoid (Salmon, "Geometry of Three Dimensions," p. 273), and Henrici's models of movable hyperboloids. Even expert analysts may make slips in their work, and may find occasionally some difficulty in detecting such slips, while an examination of a diagram or model will often indicate the mistake at once. An illustration may be drawn from Mr. Basset's statement (§142) that the circles of curvature at the ends of the minor axis of an ellipse can intersect at points which lie on the circles of curvature at the ends of the major axis; a moment's glance at a figure will show that the former circles lie wholly *outside,* the latter wholly *inside* the ellipse, for all values of the eccentricity.

Those who wish for an introductory account of the simpler properties of cubic and quartic curves will find Mr. Basset's provision for them rather scanty. His theorems (and proofs) occupy but little more space than the summary (of results only) given in Pascal's "Repertorio," t. ii. (1st edition); and some of Pascal's references are omitted from the list (for cubic curves) given on p. 100. A good deal of light would be thrown on the classification of quartics of the first species by a reference to the Sylvester-Weierstrass method of invariant factors. The same method would prove useful in handling cyclides (quartic surfaces), and leading up to Darboux's pentaspherical coordinates; as Darboux's coordinates are not introduced at all, Mr. Basset is unable to prove that confocal cyclides cut orthogonally, and various other theorems given in Salmon's account of cyclides have to be omitted also.

Nor will the inquirer after the arrangement of the twenty-seven lines on a cubic surface fare much better. Mr. Basset gives half a page to proving their existence, and that of forty-five triple tangent-planes, but he has no illustration to give us of even the simplest example of a double-six. Details of the singularities of the twenty-three different types of cubic surfaces are enumerated; but we are not told that, say, the cubic with a nodal line (of the first kind) can be illustrated by the familiar *cylindroid,* models of which are amongst the commonest examples of ruled skew surfaces.

The resolution of compound singularities (chapters iv. and v.) is discussed first for the case of plane curves; the method appears in all cases to rest on the assumption (see, for instance, §165) that the most general singularity of order [1] p can be found on a curve

[1] We have not succeeded in finding a precise definition of what Mr. Basset means by this term: it would seem to be a singular point with p tangents (some or all of which may coincide).

of degree $p+1$. But, even for $p=2$, there is at least one compound singularity not to be found on a cubic curve; this is the cusp of the second kind, the first compound singularity resolved by Cayley. And readers familiar with such investigations as those of Zeuthen ("Math. Annalen," Bd. x.), or Jordan ("Cours d'Analyse," t. i., chapter v.), will recall that it is often necessary to go to terms of quite high order before we can obtain the precise equivalents of any given singularity. It is therefore open to question whether Mr. Basset's cases really include all types of singularity, even for plane curves; and, in the case of surfaces, the method adopted is similar (see, for instance, §§194, 196), so that it is apparently subject to the same kind of objection.

Readers of Mr. Basset's "Treatise on Cubic and Quartic Curves" will recollect his fertility in the invention of new terms, such as *anautotomic, aperigraphic, endodromic,* and so on. We miss the last pair of words in the present book, but *autotomic* and *anautotomic* are to be found on nearly every page, and occasionally new phrases, such as *tritactic, quintactic, nodotangential.* The question as to whether *autotomic* is a suitable term for a surface having a conical point, must be left to experts to settle; but to an ordinary reader like the present reviewer, the word rather suggests a nodal line or curve on the surface. However this may be, the addition of an index, so that the definitions could easily be looked up, would be an advantage to the general reader not specially familiar with Mr. Basset's terminology.

T. J. I'a. B.

AMERICAN MEAT INSPECTION.

American Meat and its Influence upon the Public Health. By Dr. Albert Leffingwell. Pp. xii+208. (London: George Bell and Sons, 1910.) Price 3*s.* 6*d.* net.

DURING the early period of the year 1906 the world was startled by revolting disclosures concerning the stockyards and great packing houses of Chicago, and the conditions which were then described as prevalent were certainly a menace to the public health. Since then the general public in America and England have been under the impression that permanent and satisfactory reforms have been instituted, which have led to the rectification of the abuses then disclosed. But the writer of this work, while conceding that certain improvements have been made, finds a great deal to take exception to with reference to the quality of the meat which is produced both for home consumption and export purposes. He brings forward certain facts which indicate that laws passed in 1906 for the protection of the public health have been so construed and perfunctorily administered that in some most important particulars the Federal inspection of meat leaves much to be desired.

This tendency to favour a lax construction of the law is alleged to be perceptible in many directions. Consider lard, for an example. In the regulations of 1906, which were passed immediately after the outcry in that year, it is stated that no animals dying before slaughter could be brought into any establishment for rendering. It was intended by this regulation to keep suspected carcases away from the tanks where lard is rendered; yet in barely two years' time (April, 1908) another regulation was framed which made this prohibition dependent upon the will of an official. Again, in the 1906 regulations, extracts of meat were included with other meat-food products which were subject to the examinations required by law, yet a subsequent amendment to these regulations exempts these products from meeting the general requirements.

The author produces statistics of the number of post-mortem inspections made of carcases condemned (both in part and in whole) among cattle and hogs for the years 1907 and 1908 respectively; and certainly the statistics of the latter year indicate a marked reduction of the amount of flesh condemned.

We are also informed that the Department of Agriculture has abandoned altogether the microscopic examination of pork for the detection of trichinæ; and the author observes that the American Government now throws the responsibility of contracting this disease solely upon the consumer, if the food should not be thoroughly cooked. Furthermore, a regulation of 1906 required that carcases showing generalised inflammation of the lung, pleura, intestines, peritoneum, or uterus, whether in acute or chronic form, should be condemned; but in 1908 this was amended so as to deal only with *acute* inflammatory conditions.

In a popular work with a mission of this nature one naturally seeks for evidence as to whether the writer is fair, reasonable, and broad-minded—or otherwise. The charges placed before the reader in this work are independent of personal attestation, and they rest entirely upon official documents. The writer, however, expresses somewhat exaggerated views of the necessity for the condemnation of the whole of a carcase in which there is but strictly localised evidence of tuberculosis, malignant disease, &c. In no country in the world is this the practice; and the best scientific opinion would be opposed to the necessity for the enormous waste of good flesh which would result; although one cannot but sympathise with the sentimental objection to eating the flesh of a diseased animal.

It is a well-written and readable book, and its perusal leaves the impression that the meat inspection of the United States is far from satisfactory, and that much of what the writer says in adverse criticism of it is justified. There appears to be no doubt whatever that since the passing of the Pure Food Law, regulations governing meat inspection have been issued which, in a number of instances, considerably reduced the stringency and efficiency of the 1906 regulations.

The writer looks to foreign lands, and chiefly to England, for the remedy. He points out that the English people are vast consumers of American meat and meat products; and he asks whether the meat and meat products packed in tins and exported are likely to be derived from the best of that which passes muster. He hopes and believes that by the practical expression of public sentiment which will result in the lessened demand for such meat, in England and America, the evils will eventually be remedied.

In conclusion, it should be stated that the writer

is one who advocates "an emancipation from the enslavement of the slaughterhouse, with all its evils"; and that he holds the view "that the butchery of animals exists to-day solely because we demand the victims. We have inherited the custom from barbarism; there can be no doubt but that it will be discarded altogether by the higher civilisation of the future race."

THE CHEMICAL ANALYSIS OF IRON AND STEEL.

Die Untersuchungs-Methoden des Eisens und Stahls. By Dr. A. Rüdisüle. Pp. 395+xvi plates. (Bern: Max Dreschel, 1910.) Price 11 marks.

THE title of this book is somewhat misleading. It suggests a survey of the various methods used in the experimental investigation of iron and steel. In reality it is confined to one, viz., the chemical analysis of the constituents.

In his preface the author states that the analysis of iron and steel is one of the most difficult problems in analytical chemistry, and that his object has been to give a critical summary of the methods used in estimating each constituent, with a view to indicating which are the most trustworthy. His book certainly gives a singularly complete account of the details of the methods which have been employed in the last fifty years. But it is only here and there that any attempt is made to compare the limits of accuracy of comparable processes. A technical chemist wishing to estimate, say, phosphorus in a given steel to a certain degree of accuracy, would have considerable difficulty in making his choice from this book. Rapid methods are now the order of the day, and the works chemist has to adopt the quickest, consistent with the necessary degree of accuracy. It is a pity that the author has not borne this in mind more than he appears to have done.

As is only to be expected, by far the greater part of the book deals with the estimation of carbon, manganese, sulphur, phosphorus, and silicon, elements the percentage of which is demanded in all specifications where chemical analysis is included. In view of the detail in which carbon is treated it is surprising to find that no differentiation is attempted between "carbide carbon" and "hardening carbon" in the estimation of "combined carbon," although this is a point of considerable importance. Moreover, there is no reference to the so-called "missing carbon."

The "alloy" steels containing special elements, *e.g.* chromium, tungsten, molybdenum, nickel, vanadium, &c., are well treated, and complete methods are given for various combinations likely to be met in technical practice. There is, however, no mention of uranium, a modern constituent in the armour-plates of more than one navy.

It is significant of the neglect of the influence of gases in iron and steel that the survey of all the methods of estimation occupies only nine in a book of 380 pages. For oxygen only one trustworthy method appears to be known. Nitrogen has fared somewhat better. There is only a scanty reference to carbon monoxide and none to hydrogen and carbon dioxide. Modern metallographical research is insisting on the importance of the effect, particularly of oxygen and nitrogen, on the properties of iron and its alloys. For many years the pernicious influence of phosphorus has been recognised. It is now coming to be admitted that nitrogen may be anything between five and ten times as harmful. As yet no specifications require the estimation of the gaseous constituents in steel. The day is probably not far distant when this will be demanded.

The microscopic investigation of steels has led to another demand, viz., for a knowledge of *how* the various constituents exist in the metal. The present method of returning them as though they existed as such is entirely misleading. In the majority of cases they are combined. Some are segregated as special constituents; others are dissolved in the main bulk of the metal. It is just here that the present methods of chemical analysis are woefully weak; indeed, the researches of Carnot and Goutal stand almost alone as a praiseworthy attempt to obtain information on these matters. If the author, when he comes to prepare a second edition of his book, will include a chapter dealing with the methods that have thrown light on the chemical *constitution* as distinct from the *composition* of steels this will add considerably to the value of an already useful and trustworthy handbook.

H. C. H. CARPENTER.

THE PSYCHOLOGY OF SCIENTIFIC INQUIRY.

Erkenntnistheoretische Grundzüge der Naturwissenschaften und ihre Beziehungen zum Geistesleben der Gegenwart. By Paul Volkmann. Pp. xxiii+454. Second, completely revised, and enlarged edition. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 6 marks.

THE second edition of this work (originally published in 1896) appears as the ninth volume of "Wissenschaft und Hypothese," a series which takes its name from its first number—a translation of Poincaré's well-known essay. The author has adopted, both in the subject-matter and the mode of exposition, numerous changes that are intended to fit the book for its new *rôle*. In particular he has sought, by avoiding unnecessary technicalities and by the multiplication of examples from the history of science, to make his work useful and interesting to the layman. There is no doubt that he has succeeded. The book in its present form, though not comparable in brilliance or charm with the name-volume of the series, gives on the whole a sound and lucid treatment of the matters with which it deals. Its chief weakness is a certain lack of architectural unity and clearness of plan.

The author's general problem is to exhibit the development of science as a psychological rather than a logical process, the result of continued reaction between objective reality and investigating minds. This reaction is conditioned by certain postulates, such as the postulate of congruence between the logical necessities of abstract thought and the phenomena which express physical "law." Also it follows universally the same general course, described by the terms induction and deduction, isolation and super-

position, &c. But the details of the scientific process, and consequently its results, are a function of the mind of the investigator, as well as of the "facts" investigated. Thus there are well-defined types—especially national types—of scientific interpretation, corresponding to typical differences upon the subjective side of the epistemological relation. It follows that an inquiry into the scientific process, to be fruitful, must be based upon a study of its concrete manifestations in history.

This principle is applied in the chapters that make up the greater part of Herr Volkmann's book. The last third is devoted to an analysis of the influence of scientific thought and discovery upon the general intellectual life of our time, as represented in its philosophy, its views on education, &c. A lengthy appendix consists of a reprint of two papers, one a criticism of Newton's methods in the "Principia," the other a critical comparison between the fundamental ideas of Newton's mechanics and the alternative concepts proposed by Hertz.

OUR BOOK SHELF.

Photograms of the Year 1910. *Typical Photographic Pictures Reproduced and Criticised.* Edited by H. S. Ward. Pp. 160. (London: G. Routledge and Sons, Ltd., Dawbarn and Ward, Ltd.; New York: Tennant and Ward, 1910.) Price, paper cover, 2*s*. 6*d*. net.; cloth cover, 3*s*. 6*d*. net.

It is very useful and helpful to the photographer to have under one cover a typical set of the photographs of the year with attendant criticisms of each. It is especially valuable to those who have not had the opportunity of studying the originals for themselves. This annual should therefore be appreciated by a great number of workers, and the one now issued is a worthy follower of the former publications. In the collection here submitted the photographs have been chosen from an enormous number, and the selection, as we are told, has been made by one "who has had exceptional opportunity of considering the world's output for a quarter of a century."

This year the book has been increased by the addition of eight pages of plates, reproduced by the three-colour process from originals by the three-colour carbon method, as well as by the newer single exposure processes on autochrome, Thames, and dioptichrome plates. While the editor points out that these processes and their reproductions are not yet at the "ideal" stage of natural colour photography, they yet afford examples of the expression of artistic individuality. The book, as usual, is of an international character exhibiting photographs by Continental, Colonial, and American workers. It contains forty-eight pages of letterpress and 161 reproductions in monochrome and eleven in colours.

The "Code" School Garden and Nature Note-Book. Edited by G. Lewis. Pp. 96. (London: H. Marshall and Son, n.d.) Price 9*d*.

This little note-book is intended to help the scholar and the teacher in systematising the work and the observations in the school garden. Unless a careful record is kept, the full educational value of many of the observations cannot be obtained, but there may be some difficulty in keeping the records in such a way that they shall be readily accessible. This difficulty is obviated in the present book. The main part of it is divided into twelve parts, one for each month, each consisting of five pages. On the first are a few reminders for the month, showing what should be done in the fruit, flower, and vegetable gardens, what the animals and birds are doing, and what to look for in wild plant-life. The next two pages are for a record of work done in the garden; the fourth is ruled up for meteorological observations, but as only fourteen entries can be made it is clear that daily readings are not contemplated. The last page is for nature observations. At the end of the book are pages for crop records, for temperature and rainfall charts—one for atmospheric pressure might usefully have been added—and for profit and loss account.

The mechanical labour of keeping observations is thus reduced to a minimum, and at the same time the record can always be traced back if necessary. Only those who have attempted to get together class records can realise entirely what a saving of time and trouble this means.

One or two points in the introductory pages want alteration. A loam is not "a soil composed of equal parts of clay and sand." It is not only unnecessary, but undesirable, to give the name "sulpotide" to the definite and well-known sulphide of potassium wash; if the scholar or teacher looked in the index of a standard gardening book he would hardly be likely to see the word mentioned. The author recommends the injection of carbon bisulphide into the soil to kill the larvæ of the click beetle (wireworms); this is hardly a school operation, even if it were effective, and the evidence on this point is by no means clear. But apart from these little points the book is very useful, and can be commended for class purposes.

Handbuch der vergleichenden Physiologie. Edited by Hans Winterstein. Band ii., Erste Hälfte. Neunte Leiferung. Physiologie des Stoffwechsels, Physiologie des Zeugung. Pp. 819–980. Band iii. Zweite Hälfte. Zehnte Lieferung. Physiologie der Energieproduktion. Physiologie der Form. Pp. 161–320. (Jena: Gustav Fischer, 1910.) Price per fasciculus 5 marks.

When the earlier fasciculi of this ambitious work appeared, we noted the general characters and aims of the undertaking. The ninth fasciculus contains a continuation of Prof. W. Biedermann's article on nutrition in the different classes of the world ot life; but the article in question is not yet concluded. Each group is considered in detail, and the outcome will be a most valuable work of reference, and contains a mine, not only of information, but of references to original researches. The bibliographical notices relating to digestion and nutrition in the insects and myriapods alone number 247.

The tenth fasciculus is a portion of the third volume, which deals with quite different subjects. No doubt it is a convenience to the editor to print the bits as they are ready, though it is a little confusing to the reader. It contains portions of two articles; the first is the conclusion of an article on the production of electricity in animals and plants, by Prof. S. Garten, and the second the commencement of an article by Prof. Ernst Mangold, on the production of light in living things, especially in animals. The two articles manifest the same thoroughness of treatment noticeable in the previous fasciculi, and we congratulate the editor on having secured the service of collaborators who are all actuated by the same high ideals.

Guide to the British Vertebrates Exhibited in the Department of Zoology, British Museum (Natural History). Pp. vii+122, with a plan and 26 illustrations. (London: Printed by order of the Trustees of the British Museum, 1910.) Price 1*s*.

This guide contains a concise account of the British vertebrates other than the turtles and marine fishes,

which are altogether omitted, and the Cetacea, of which only a list is given. The seventy-five species of mammals are dealt with in an interesting manner, references being made to their habitat, food, care of young, change of coat, hibernation, &c. The common and Latin name of each species is given, and we are glad to note that where the Latin name has recently been changed the older and more familiar designation has also been added. The large number (442) of birds in the British list necessarily means that each can receive only comparatively short notice in the space available; nevertheless, a large amount of interesting information is packed into the twenty pages devoted to this part of the subject. The reptiles—three snakes, the blind-worm, and two lizards—and the Amphibia, seven in number, are described, with notes on their distribution and habits. The account of the fishes, which is restricted to those occurring in fresh water, also contains many interesting observations on their distribution, the distinctions between allied species, spawning, &c.

An appendix contains a full list of the species of vertebrates, other than turtles and marine fishes, which have been recorded from the British area. In the case of those birds which have occurred not more than six times notes are added or references given to the records of capture. The illustrations, about half of which are reproduced from photographs, are good, and several are of special excellence. The volume forms a thoroughly serviceable guide to the collection.

The Sea-Kings of Crete. By the Rev. James Baikie. Pp. xiv+274. (London: A. and C. Black, 1910.) Price 7*s.* 6*d.* net.

As a compilation this work shows great diligence; it has evidently been written *con amore,* and its aim is most praiseworthy; but it has no scientific value. We prefer to see *œuvres de vulgarisation* of this kind written, when possible, by the excavators themselves. This is no doubt a counsel of perfection; they have usually too much to do to write popular books. But in any case, such books should only be written by trained archæologists with a first-hand knowledge of the subject and a personal acquaintance with Crete itself. Of these qualifications we do not see much evidence in Mr. Baikie's work, which, after the publication of the books of Mrs. Hawes (a Cretan excavator) and Prof. Burrows, seems scarcely needed.

Pinro. (Brook's patent.) (W. J. Brooks and Co., Letchworth, Herts.) Price 1*s.* per twelve yards.

THIS device consists of a thin metal tape, from which fine steel points project at intervals of about four inches. It is intended to be used by draughtsmen as a substitute for drawing-pins, and also for attaching canvas, posters, fabrics, &c., continuously along the edges. The contrivance does not seem to us likely to be generally adopted, but there are special circumstances under which it might be found very serviceable.

Teachers' Notes on Nature-Study: Plants and Animals. Pp. viii+232. (London: Blackie and Son, Ltd., n.d.) Price 1*s.* 6*d.* net.

THIS re-issue of an old work will not commend itself to teachers who desire to make the school study of science a training in accurate observation, simple reasoning, and precise expression. The method of teaching, the haphazard arrangement of subjects, and the general absence of scientific treatment, all remind the reader of the discredited style of "object-lesson" common ten or fifteen years ago. The compiler, whose name is withheld, does not appear to realise the necessity in the case of young pupils for basing every lesson on plants upon specimens in the hands of each child, and encouraging the children to draw from the specimen rather than from the teacher's blackboard sketches.

The Scientists' Reference Book and Pocket Diary for 1911. (Manchester: J. Woolley, Sons and Co., Ltd.) Price 1*s.* 6*d.*; bound in morocco, 2*s.* 6*d.*

IN addition to a handy diary in which provision is made also for memoranda and addresses, this publication provides a very useful book of tables and facts likely to be of use to workers in science, as well as to students. In view of its small price the combination is likely to secure a wide popularity.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Historical Note on Recalescence.

THE interesting *résumé* of Prof. Arnold's British Association paper on recalescence, which appeared in NATURE for December 1, contains the following statement in the opening paragraph:—

"In 1868 the late Dr. Geo. Gore, F.R.S., discovered the recalescent points now known as Ar_3 and Ar_2, and in 1872 Prof. W. F. Barrett, F.R.S., discovered the recalescent point Ar_1, which is now known as the carbon change point. Prof. Barrett gave the phenomena the generic title of 'recalescence,' by which they have been known ever since."

As no little misapprehension exists on this subject, it is desirable, as a matter of historical accuracy, to state that Dr. Gore did not discover the phenomenon of *recalescence,* but he was the first to observe the remarkable momentary elongation of an iron wire during cooling from bright incandescence, which important observation subsequently led to the discovery of recalescence.

Owing to the great practical importance which recalescence has assumed in the hardening and heat treatment of steel, it may perhaps be of interest if I briefly state the early history of this discovery.

The Proceedings of the Royal Society for January 28, 1869, contains a paper by Dr. Gore which records the anomalous behaviour of cooling iron above referred to—its sudden transient expansion at a dull red heat. This anomalous behaviour Dr. Gore found was not shared by other metals, and he states that no reverse effect was noticed upon heating iron wire to incandescence.[1]

Some two years later, having to deliver a lecture before the Royal Dublin Society on the "Molecular Changes that accompany the Act of Magnetisation," I was anxious to show Mr. Gore's interesting discovery, as it appeared likely to be connected with the resumption of the magnetic state in iron when cooling from a white heat. In answer to my inquiry Mr. Gore kindly furnished me with his apparatus, and as he said he had no further use for it I purchased it from him, and it is still in my possession. To make the effect visible to a large audience a mirror was attached to the spindle which moved the index, and from it a ray of light was reflected to a distant scale. This device revealed the fact, overlooked by Dr. Gore, that a small momentary *contraction* of the iron wire took place during its heating to incandescence, approximately at the same temperature at which the momentary elongation occurred in cooling.[2]

Dr. Gore having informed me, in a letter dated May, 1872, that he was not pursuing his original observation and that the subject was quite open to anyone, I felt at liberty to continue the inquiry. Accordingly, the following year, Dr. Guthrie having kindly placed his laboratory

[1] In fact some eighteen months after his original observation Dr. Gore states in a paper published in the *Phil. Mag.* for September, 1870 (the italics are his):—"The iron during cooling . . . suddenly elongated by diminution of cohesion . . . a corresponding but reverse phenomenon did *not* occur during the process of *heating* the wire."

[2] This lecture was repeated at the London Institution a year later, and a full report of it is published in the Journal of that Institution.

at South Kensington at my disposal, an investigation was begun, which led to the discovery of recalescence on September 12, 1873. On that date I noticed that accompanying the Gore effect in cooling iron, and at the same critical temperature, a sudden reheating or *after glow* occurred. It was more difficult to detect the reverse effect on heating, but a momentary arrest of the heating appeared to occur at the critical temperature. The Chatelier thermo-electric pyrometer was unknown at that time, and I had to have recourse to an air thermometer, which showed that the after glow was not an optical illusion, but a real, though transient, accession of temperature, due to a liberation of latent heat and not to surface oxidation of the iron, as was shown by the recalescence occurring as strongly in an atmosphere of nitrogen or other inert gas as in air. Furthermore, this effect appeared to synchronise with the critical temperature at which iron lost on heating and regained on cooling its magnetic power, and with the remarkable thermo-electric inversion in iron which Prof. Tait had then recently discovered. I noticed, also, that a crepitation occurred in the iron at this temperature resembling the Page effect on magnetising iron.

These and other observations were described, and the experiments exhibited at the British Association meeting at Bradford a few weeks later, September, 1873, and the paper was published in the *Philosophical Magazine* for December, 1873.[1] An interesting discussion on recalescence followed the reading of my paper, in which Prof. Clerk Maxwell, Mr. Herbert Spencer, Prof. Carey Foster, and others took part. This was reported in the local papers at the time, and happily is preserved in a number of the now defunct *Quarterly Journal of Science*.[2]

Later on a British Association Committee was appointed to report on the whole subject, Prof. Geo. Fitzgerald being chairman and myself secretary. Unfortunately, a long delay occurred in the publication of the report, partly owing to my removal to Dublin and the pressure of work in the chair to which I was appointed; meanwhile, the subject was greatly enriched by the researches of others, especially by M. Osmond, who in 1886 made it the starting point of his classical investigations. An interim report by the British Association Committee was, it is true, published, but I would specially refer to the final lengthy report published in the Proceedings of the British Association for 1890, which had the advantage of Prof. Geo. Fitzgerald's cooperation, he having witnessed and corroborated some of the earlier experiments described therein. It is there shown that in 1875 two recalescent points were found, most markedly in steel wire, "the second and far stronger after glow being exactly coincident with the sudden elongation of steel wire during cooling" (the Gore effect). As that report is easily accessible, I will not refer to the other observations it contains. Amid the large literature on this subject which has grown up attention should be directed to an excellent investigation by a Swede, Dr. G. E. Svedalius, on the "Measurement of the Anomalous Changes in the Length and Temperature of Iron and Steel during Recalescence"; this was communicated by Prof. Geo. Fitzgerald to the *Philosophical Magazine* for August, 1898.

With regard to the allotropic form of iron which appears to be produced at high temperatures—Osmund's β iron—and the liberation of the latent heat of allotropy during cooling causing recalescence, I may point out that Prof. Tait, from his thermoelectric researches, had been led to the conclusion, as stated in his Rede lecture in 1873. "that iron becomes a different metal on being raised above a red heat." But I believe Prof. Geo. Forbes was the first to suggest and publish the fact that recalescence might be due to the liberation of the latent heat of an allotropic form of iron. Writing to me upon my experiments on April 18, 1874, he remarks:—"It would follow that iron heated to an intense white heat assumes an allotropic form, and that at this temperature [of recalescence] when cooling it changes to the other form and gives off latent heat."

In conclusion, let me congratulate Prof. Arnold upon his investigations, extending over so many years, and the light he has thrown on the causes of the different phases of recalescence and the importance of the carbon change point. No doubt he is aware that M. Svedelius, in the paper referred to above, also experimented with electrolytic iron. Referring to the expansion at the critical temperature, Svedelius says:—"In a rod of electrolytic iron the magnitude of the expansion at D_1 decreased very rapidly with every renewed heating, and after the fiftieth heating no trace either of the critical point D or D_1 could be discovered"; and he adds in a footnote:—"This confirms the statement made long ago by Prof. Barrett that in very pure iron the anomalous contraction and expansion could be 'washed out,' as it were, by repeated heating and cooling." I do not know whether Prof. Arnold has experimented with a very low carbon "burnt iron" to ascertain whether any recalescent points remain in such iron.

W. F. BARRETT.

Kingstown, co. Dublin, December.

[1] "On Certain remarkable Molecular Changes occurring in Iron Wire at a Low Red Heat. *Phil. Mag.*, December, 1873, p. 472; see also my paper in the following number of the *Phil. Mag.*

[2] Upon the publication of my paper in the *Phil. Mag.*, Dr Gore wrote to me as follows, in a letter dated Edgbaston, December 22, 1873:—"Your new discoveries respecting the molecular changes in iron, described in the *Phil. Mag.* for this month, have greatly pleased me; especially the sudden development of heat attending the elongation during cooling, and the sudden shortening during heating." Furthermore, when Sir Roberts-Austen in a lecture before the British Association in 1889 made much the same error as that quoted at the beginning of this note, Dr. Gore at once wrote to me and expressed his great surprise that the discovery of recalescence should be attributed to him.

Captain Cook Memorial.

UNDER the auspices of the British Empire League, a very representative and influential committee has been formed to carry out the proposal made by Sir Joseph Carruthers, K.C.M.G., ex-Premier of New South Wales, that a monument should be erected in London to the memory of Captain Cook; but I venture to ask. is this the best way to honour the memory of the illustrious navigator? Captain Cook was a great seaman, geographer, and ethnologist; indeed, he was one of the foremost of the men of science of his day. As his life was devoted to discovery of various kinds, surely the best memorial to him would be to establish a fund, associated with his name, the interest of which should be devoted to the prosecution of investigations analogous to those in which he spent his life and met his death.

Cambridge, December 13.

A. C. HADDON.

Accuracy of Time on Magnetograms.

I AM greatly interested by Dr. Krogness's letter in NATURE of December 8 directing attention to this matter. We have been investigating this point for some time by interrupting both trace and base line in our Adie magnetographs.

We find that, in general, if the times are taken from the base line we should actually get declination for about two minutes later, but horizontal force and vertical force for two minutes earlier. The error is probably not constant, and so we have decided to interrupt the trace. It may be of interest to say that we have been able to reduce the interruption to one minute, which corresponds to $\frac{1}{4}$ mm. on the paper.

GEORGE W. WALKER.

The Observatory, Eskdalemuir, Langholm, Dumfriesshire, December 19.

The Quadrantid Meteor Shower.

IF the maximum of this meteor shower should occur when the earth is in the same position with regard to the sun as was formerly the case, it would take place in the daytime of January 3, 1911, but this shower does not seem to have been sufficiently watched of late years to ascertain when the maximum now occurs. There is, however, some reason to believe that it will not be until the evening of January 3, in which case, as there is no moonlight, it would be a very favourable opportunity for its observation in this country. As the maximum is of short duration it ought to be more extensively watched for annually than appears usually to be the case.

T. W. BACKHOUSE.

West Hendon House, Sunderland, December 13.

ORIENTAL OR BUBONIC PLAGUE.

PLAGUE is an acute infective disease, an infectious fever, attacking man and some of the lower animals, and attended with a considerable mortality. The symptoms in man develop within a few days of infection, and consist of fever, headache, giddiness, weakness, with staggering gait, great prostration, and delirium. In 75 per cent. of the cases the lymphatic glands in the groin, armpit, and other regions are inflamed, infiltrated, and much enlarged, constituting the "buboes," hence the name "bubonic plague" frequently given to the disease.[1] In the remaining cases, the lungs may be primarily attacked, the "pneumonic" form, or a severe blood infection may develop, the "septicæmic" variety; in both of these buboes are absent, or are a late development if the patient lives. Occasionally an eruption of pustules or carbuncles appears on the skin, a phenomenon frequently mentioned by the older writers, and abscesses may form in the buboes. The bubonic form is hardly infectious or even contagious, but the pneumonic variety is highly infectious, owing to the presence of large numbers of the infective agent, the plague bacillus, in the expectoration from which it is readily disseminated in the air. In some instances the patients do not appear particularly ill, and are able to go about, though such cases are liable to sudden death from heart failure.

The micro-organism of plague was discovered independently by Kitasato and by Yersin in 1894. It is a stumpy, rod-shaped organism or "bacillus," having rounded ends, and measuring as a rule about 1/8000 inch in length, and 1/16000 inch in breadth, but longer forms occur. In smears made at an early stage of the disease from the buboes, expectoration or blood respectively in the three varieties, the bacillus is present in enormous numbers, and if the films are stained with an aniline dye, such as fuchsia, it tends to stain deeply at the ends ("polar staining"), the centre being hardly stained at all (see Figs. 1 and 2); this is a very characteristic appearance. In older lesions peculiar, large, rounded or ovoid "involution" forms of the bacillus are met with. The organism can be readily cultivated in various media in the laboratory; it is non-motile, and does not spore, and is readily destroyed by heat (60° to 65° C. for ten to fifteen minutes), and by disinfectants. The plague bacillus is pathogenic for a number of animals, in addition to man—the rat, mouse, guinea-pig, rabbit, hare, ferret, cat, monkey, &c. In the United States the ground squirrels are attacked.

A remarkable feature which has characterised plague from the earliest times is the alternation of periods of widespread prevalence, "pandemics," with periods of quiescence and complete intermission. Thus, in the fourteenth century, in the course of three years, plague decimated the whole of Europe, with an estimated destruction of one-fourth of the population, appearing in England as the black death.[2] In the fifteenth, sixteenth, and seventeenth centuries there were frequent outbreaks in Europe, Asia, and Africa, more or less limited in extent, culminating in England in the great plague of London, with 97,306 burials in 1665, of which 68,596 were attributed to plague, whereas in the five years preceding and succeeding this terrible visitation the normal number of burials in London ranged from about 15,000 to 20,000. Plague then rapidly disappeared from western Europe, so that by the end of the seventeenth century it was practically extinct, and save for isolated outbreaks (*e.g.* at Marseilles and Toulon in 1720) occurred only in Turkey, the Levant, Egypt, and Asia Minor. Thus plague was practically unknown to the present generation until 1894, when it reappeared in epidemic form, this time in Hong Kong. There have always been localities in which plague has been "endemic," *i.e.* continuously prevalent, for example, on the Persian Gulf, in Asia Minor, and in Yunnan, a province of China bordering on Burmah and Tibet. According to Prof. Simpson, plague travelled from Yunnan by the overland trade routes to Canton, thence by river to Hong Kong; from Hong Kong the disease was sea-

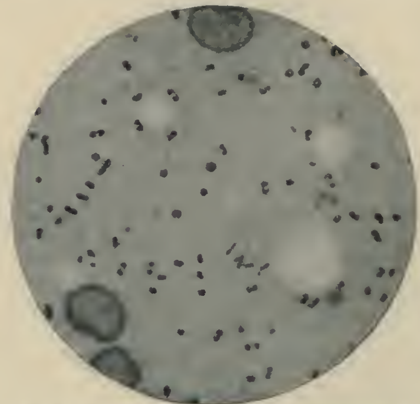

FIG. 1.—Smear from bubo showing large numbers of plague bacilli. ×1200.

borne to India, where it certainly appeared in 1896, and since then has similarly been carried all over the world. The agent by which the disease has been so widely disseminated is the rat, infection from man to man being almost negligible, the rat fleas being the intermediaries between the rat and man, and mechanically conveying the infection—the plague bacilli—from rat to rat, and from rat to man (*vide* an article by Dr. Petrie in NATURE, November 3, p. 15). For combating the spread of plague, the destruction

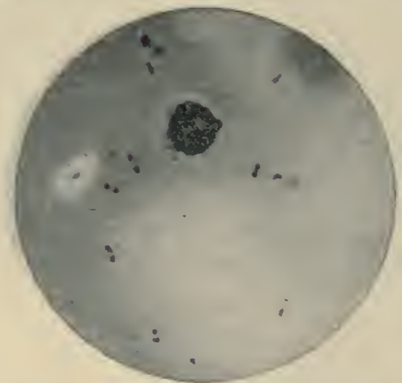

FIG. 2.—Smear from spleen of infected Ferret (from Suffolk), showing typical bi-polar staining plague bacilli. ×1200.

of rats is therefore an important measure. While it seems hopeless to effect complete destruction of these rodents, a great deal can be done to lessen their numbers, and the survivors will probably be less likely to be infected. The destruction of rats may be carried out by systematic trapping, ferreting, and poisoning, but anyone who has had to deal with rats is aware how "cute" they are, and the most tempting morsels will often fail to attract them to trap or poison. Handling the material or trap is sufficient to rouse their suspicion, and the "taint" of man, if present, must be destroyed by flaming or disguised by the use of

[1] Although this is the rule, Prof. Simpson points out that in Accra, West Africa, 50 per cent. of the cases were of the pneumonic variety.
[2] I am indebted to Prof. Simpson's "Treatise on Plague" for these and other historical details.

some strong-smelling substance, such as aniseed. Moreover, after a few rats have been caught or poisoned in a locality, the survivors will frequently migrate elsewhere, hence the need for concerted and systematic action in and around a district in which plague has occurred.

Although plague cases may occur at any time of the year, the disease usually exhibits a marked seasonal prevalence. In Poona plague is epidemic only from July to February, August, September, and October being the months of maximum prevalence. This period corresponds closely with the extent of flea prevalence on the rats. An epidemic terminates naturally, owing to a combination of adverse factors, *e.g.* decrease in the number of fleas, decrease in the number of rats, and an increase in the proportion of immune to susceptible rats.[1] In some instances plague cases may be completely absent between the seasons of prevalence, but by what means the infection is kept alive in the intervals has not yet been determined. Rats are occasionally met with suffering from what has been regarded as chronic plague, but the latest investigations of the Indian Plague Committee indicate that the condition is one of recovery from plague infection, and the condition is stated to possess no significance in the seasonal recurrence of the disease among the rats.[2]

The recent outbreak of plague in Suffolk, though in itself insignificant, is disquieting owing to the fact that plague-infected animals—rats, rabbits, hares, a ferret (see Fig. 2), and a cat—have been met with in five districts in Suffolk, in one district in Essex, and in the London Docks, indicating a somewhat wide distribution of infected localities. This may be of no moment, but, on the other hand, it may in the future lead to scattered outbreaks of human plague, probably not in themselves very serious, but possibly causing great injury to commerce. Thus, if, say, half a dozen cases of plague occurred in the neighbourhood of the docks, the Port of London would be placed in quarantine,[1] and the home and foreign trade of the port amounts nearly to *one million pounds per day!* It behoves the authorities therefore to prosecute a vigorous, concerted, and systematic campaign against the rats with a view to the detection and the limitation of infected areas; now is the time for action, for when infection becomes widespread it is too late.

For the photo-micrographs I am indebted to Mr. J. E. Barnard. R. T. HEWLETT.

EXPLORATION IN THE NEARER EAST.

IN his latest book,[2] Mr. Hogarth has given us a series of brilliant sketches, each of which centres round some episode in a life of very varied archæological adventure. It is a delightful form of autobiography, for we find no dull pages to skip, no laboured accounts of worthy but uninteresting achievement. Each chapter is a separate picture in itself, and, as we read, we find ourselves transported, with somewhat startling rapidity, throughout the lands of the Nearer East. We see the author at work as an archæologist on the coasts of Asia Minor, in Crete, among the Nile fens of the Delta, in Upper Egypt, on the North African coast at Cyrene, and by the banks of the Euphrates and Sajur, to say nothing of the time when he served as the *Times* correspondent in Thessaly during the Græco-Turkish war. Few archæologists, if any, have accomplished work of so

FIG. 1.—Rigging the great Pump at Ephesus. From "Accidents of an Antiquary's Life."

varied a character, and certainly none has Mr. Hogarth's gift of vivid narrative. Many readers will doubtless be surprised that the study of archæology should prove so attractive and picturesque an occupation, but it is not without its hardships, as Mr. Hogarth's pages bear witness. Saddle-sores, poor food, the necessity to keep going even when half-dead with malaria, and the absence of skilled advice when suffering from other ailments, have to be faced by anyone who would take part in the exploration of the less accessible countries of the Nearer East. But Mr. Hogarth lays no undue stress on what he has undergone, and in his introductory chapter, which he entitles an "Apology of an Apprentice," he examines the basis of the faith that has sustained him.

FIG. 2.—Half Buried Palm-forest, Baltim. From "Accidents of an Antiquary's Life."

We do not pretend to an opinion as to whether an antiquary, like a poet, is born, not made, but there can be little doubt that careful training may do much to mould an original, though perhaps latent, inclination. Apart from the fact that he is more curious of the past than the present, Mr. Hogarth well describes the antiquary as loving detail for its own sake and as caring less for ends than means. His ideals are, in fact, rather different from those of the purely scientific mind. The severe man of science may extol the pursuit of knowledge for its own sake, but at the back of his mind there is always an idea of benefiting somebody or something. The true antiquary has no such obsession. The results of his labours, when set out and labelled in public museums, may perhaps have an educational value—archæology may after all be the handmaid of history—but to him the pursuit is an end in itself apart from its results.

FIG. 3.—The Theatre of Aspendus. From "Accidents of an Antiquary's Life."

Though such may be the philosophy of "the antiquarian trade," Mr. Hogarth does not fail to recognise that plunder is a real incentive, even to the most

philosophical of inquirers; and the material results of his own explorations give them a satisfying completeness, like the buried gold which should always reward the treasure-seeking hero of romance. One of the most exciting episodes in the volume, the exploration of the limestone cave on Dicte, the legendary birthplace of Zeus, affords an instance in point, and shows how unexpected may be the treasure that sometimes awaits the fortunate explorer. Having blasted a way into the cave through the fallen rock and boulders that blocked its entrance, a fortnight's careful search of the soil in the upper cave was rewarded by a certain number of votive offerings around an altar of burnt sacrifice. But it was at the end of the excavation, when it only remained to search the lower cave for objects that might have slipped down during the secret digging of the past few years, that the element of luck came in. The floor of the lower cave is covered with an icy pool which runs far into the hill about the bases of fantastic stalactite columns. Here, Mr. Hogarth tells us, he did not expect to find much spoil, since no native had ever found anything in the pool among the columns, except a few scraps of water-borne pottery from above. But with the true archæologist's instinct of seeing for himself, Mr. Hogarth ordered a thorough search. Not much was found in the pool itself, but a zealous worker, wanting to put both hands to his work, happened to wedge his candle-end in the fluting of one of the stalactite columns, and by its light he perceived the green edge of a bronze blade in the slit. A further search was at once ordered:—

"Men and girls dispersed themselves along the dark aisles, and perching above the black waters on natural crockets of the pillars, peered into the flutings. They found at once—found blades, pins, tweezers, brooches, and here and there a votive axe, and in some niches as many as ten votive things together. Most were picked out easily enough by the slim fingers of the girls; but to possess ourselves of others, which the lights revealed, it was necessary to smash stalactite lips that had almost closed in long ages."

These were all votive objects, placed on the columns of that silent pool that formed the shrine of the god of Dicte. "As we saw those pillared aisles," Mr. Hogarth remarks, "so with little change had the last worshipper who offered a token to Zeus seen them three thousand years ago."

Another venture that was crowned with unexpected spoil was the excavation of the great Artemisium at Ephesus, when the resources of modern engineering had to be invoked to pump out the flooded excavation around the base of the "Great Altar" and the foundation-deposit. The illustrations to the volume, unlike those in so many modern works, really illustrate the text, and each fits naturally into the narrative. Of those we have chosen for reproduction, one shows the rigging of the great pump at Ephesus; another, representing a half-buried palm-forest at Baltim, well illustrates the constant eastward progression of the shifting sand-dunes which fringe the great flats of the Nile delta; the other, taken in the theatre of Aspendus in Pamphylia, forms a striking contrast to the Ephesus photograph, and shows the remarkable state of completeness in which a building of classical antiquity may be preserved. Of all Roman theatres this is perhaps the most perfectly preserved example.

The book contains several good stories, such as that of the young British subaltern who knew no word of Greek, but arrived on a polo pony "to be a father to some twenty Cretan villages," and whose judgments, delivered in knickerbockers and a cricket shirt, were worthy, in their practical aspects, of a Solomon. But we have already trangressed the space allotted to us, and in any case we would not quote or summarise the many passages we have marked. We prefer to leave them unspoiled for the reader, to whom, whether he be of an archæological bent or not, we warmly recommend the volume as excellent reading.

L. W. K.

ANTI-MALARIAL MEASURES IN INDIA.

A PERMANENT committee dealing with anti-malarial measures in India has been appointed by the Government of India. Its members are Lieut.-Col. Leslie (Sanitary Commissioner with the Government of India), Major James, I.M.S., Captain Christophers, I.M.S., and Lieut.-Col. Semple. Excluding the last-named, whose views on the matter have not yet been made public, the members of the committee, previous to their embodiment, allowed it to be understood that, in the light of the reputed failure of the Mean Mir "mosquito reduction" experiments of 1901–3, they hold any effort beyond quinine prophylaxis as rarely applicable to India. Indeed, they claim that conditions in that country are so different from those found in other parts of the world that further investigations—and not application of elsewhere approved anti-malarial measures—is the necessary *rôle*.

An earnest of this attitude is exhibited in the publication by it, under the auspices of the Government of India, of a brochure entitled "Paludism," which it is announced will appear at irregular intervals—as results from its labours become available. The editor (Major James) in describing the functions of the committee and its relation to Sanitary Departments and local bodies under provincial Governments, states that the conference on anti-malarial measures in India, held at Simla in 1909, "strongly supported the establishment of this organisation." The terms used by the editor, however, seem unduly optimistic. A reference to the Proceedings of that conference shows that the appointment of this committee was not open to option, but was definitely announced as an accomplished fact by the Government of India; and that there are recorded marked objections by members, not to the existence of the committee as a scientific body, but to its possessing the extraordinary administrative power to "direct (*sic*) and coordinate investigations" throughout India, which, in the presence of Indian official methods and the huge area involved, cannot fail not only to trammel the initiative of local Governments and their Sanitary Commissioners, but must hopelessly delay the execution of practical measures.

Although, doubtless, having regard to the excellent *personnel* of the committee, the publication will from time to time furnish scientific matter of value, in the absence of insistence by the Government of India that practical anti-malarial measures be undertaken, public opinion will be apt to hold that its primary function is that of a convenient financial scapegoat. The first number of *Paludism,* after referring to the functions of the committee, affords an original paper by Captain Christophers on the use of statistics in investigating the epidemiology of malaria, and gives abstracts of papers relative to paludism *in countries other than India.*

In the meantime, sanitarians with no lack of local experience have failed to see that there is in the environment of the mosquito in India more startling conditions than have been met with and overcome elsewhere. Major Ross, C.B., especially, has from time to time called in question the correctness of the Mean Mir experiments; and, in person, he challenged the methods and conclusions of the officers concerned

at the Indian Medical Congress held at Bombay in 1908. It was therefore a wise decision on the part of the Government of India, on the termination of the Simla anti-malarial Conference of 1909, to depute a special committee of inquiry on this subject. The officers selected were the Hon. Mr. Nathan, I.C.S., Colonel Thornhill, I.A., and Major Leonard Rogers, I.M.S. Whilst all its deductions cannot be accepted, this committee has produced a report which, though omitting important details, is a remarkable product of a single month's work. The experimenting officers, Major James and Captain Christophers, apparently elected to test statements made by Major Ross, and regarded Mean Mir as a suitable locality for this object. Of several typical extracts from his publication and speeches quoted in the report as justifying their methods, the following is selected as of the most definite nature:—

"It is now a matter of the general experience of many investigators that where mosquitoes abound in a house their larvæ can easily be found at a short distance, say within a few hundred yards of the house. Occasionally, where the house is isolated and no stagnant water is in its immediate vicinity, mosquitoes may attack it from a greater distance; but this is exceptional, and in the great majority of cases, especially in towns, almost every house breeds its own mosquitoes in its backyards or in puddles or drains in the streets close by."

To meet the necessities of a test experiment guided by such very general data, it would have been well, whilst relying upon the importance of the observation as to pools in the vicinity of houses, also to have ascertained from the authority concerned what he implied by a "few hundred yards" of the house and even "a greater distance"; especially as by making pools unfit for the reception of larvæ by "oiling" in the neighbourhood of houses, there was fulfilled—so far as the mosquito is concerned—the condition that "no stagnant water" be available in that position.

The area selected by Major James was an oblong—and not an isolated—portion of two square miles of the total of eight square miles of the cantonment of Mean Mir, whilst the line defining its limit, except on the west, was "drawn close round the residential quarters, no attempt being made to deal with the outlying uninhabited areas." The map furnished with the report proves that the distance of dwellings from untreated portions of the cantonment varied from 40 to 260 yards, and that the limiting line abruptly excluded numerous pits and rain-fed depressions. It is a curious commentary upon this haphazard method of conducting an important experiment that Dr. Balfour, in his successful work at Khartoum, did not similarly interpret Ross's dicta with which he professed agreement.[1]

More reasonable measures were, however, employed by Captain Christophers when operations fell under his charge. He found that the flight of the mosquito could be estimated at 1320 yards, and, thereupon, he reports, he extended the area maintained by Major James three-quarters of a mile "in every direction."[2] Unfortunately, however, action was not taken by him on this basis until the end of August, 1903, which, having regard to the duration of life of the mosquito, was perilously close to the ensuing three months known locally as the "fever season." Moreover, on comparing the map accompanying his own report with that furnished by the committee, it will be seen that confusion exists as to the essential point of measurement being made from the most external of the houses of groups of dwellings protected, and not, for example, "from the centre of the inhabited area"—a method which seems to have been erroneously adhered to by the reporting committee. Comparative measurements show that, in reality, he extended Major James's area 220 yards in the north, 465 yards on the west, 500 yards in the east, and a little more than three-quarters of a mile on the south. Yet, had the same solicitude been afforded in other directions as to the south, so as to secure a uniform extension of three-quarters of a mile "in every direction," there would have been included the native cavalry lines, the west infantry lines, the east native infantry lines, the lowlying dhobies' ground, and part of the pits of the east rifle range.

The map showing present conditions, and the accompanying description by the committee of work done in the filling of pits, subsequent to abandonment of the experiments by Captain Christophers, prove that under this arrangement there must have remained untreated very numerous and favourable spots for larvæ. The committee, in summing up its evidence, has recorded its opinion that mosquito reduction, under conditions prevailing in Lahore, was impossible; but it seems to us clear that the experiments were based upon an erroneous interpretation of data said to have been adooted for guidance, and, in execution, so lacking uniformity of method as to be of no sanitary value.

On completion of the "mosquito reduction" experiments at Mean Mir, the Government of India left the cantonment to its fate until Surgeon-General Hamilton, C.B., urged the employment not only of "mosquito reduction" methods, but the systematic improvement of surface drainage, the abolition of canals, and irrigation within a definite (but we think insufficient) radius of dwellings, and the employment of quinine prophylaxis. This highly practical advice met with warm support from General Kitchener, who was in charge of the division, and operations were accordingly carried on from 1904 to 1909. Nevertheless, those who would support a *laissez-faire* policy in India have declared that these efforts have also proved inapplicable. But, it is evident from the committee's report that in no detail has the advice of Surgeon-General Hamilton, up to date, been acted upon in so complete a manner or with such a grade of efficiency as would warrant final conclusions as to possible benefits.

In its conclusion, the committee holds that the "general prosecution" of major schemes, such as conducted in Panama, Lagos, and Sweetenham, is financially impracticable; it regards anti-larval measures combined with quinine prophylaxis as offering "great possibilities," and advises action by Government on this system, but would defer this pending investigations by the committee referred to above, in our notice of *Paludism*. For the rest, it would trust to education of the people, which they state "thus lies at the root of the problem." There is here therefore a diminution of hope as to practical measures by a process of whittling, and a suggestion of the Greek Kalends as to consummation. In using the term "general prosecution" of schemes, the committee has presumably laboured under the common misapprehension that sanitarians would desire the sudden expenditure of crores of rupees on anti-malarial "major works" throughout India. What, however, is pleaded for is that the Government of India should no longer be guided by results of experiments conducted at Mean Mir by haphazard methods, and thus fail, as it has for several years—apparently in

[1] Second Report Wellcome Research Laboratories (Khartoum), p. 21.
[2] Scientific Memoirs by Officers of the Medical and Sanitary Departments of the Government of India, No. 9, p. 8.

consequence of advice founded on such results—to insist that local governments and local bodies serving under it shall no longer fail to class anti-malarial measures as practicable, but shall estimate for and finance them when feasible.

As to the combined anti-larval measures and quinine prophylaxis, of the "great possibilities" of which the committee is hopeful, obviously they could be conducted continuously, at the least feasible cost, by the Government of India insisting that a correctly organised and well-educated executive sanitary service should be available in each province, as, if the still incomplete service in the Madras Presidency be excepted, not even the skeleton of such an organisation yet exists in India.

As for "education," the only form that will appeal to the average Indian villager for the next century is practical demonstration of what correctly conceived anti-malarial works can accomplish. His acquiescence in Western *theories* would be but a polite fiction, although no race can more quickly, or more gratefully, appreciate sanitary works demonstrably decreasing sickness and death; nor, in the face of his conviction as to their utility after their completion, would he grudge his contribution towards them.

Municipalities do at the present time undertake large sanitary works (other than anti-malarial) at a cost from Rs.4 to Rs.12 per head of the population served. But it is apparently the typical "small town" under district board jurisdiction that presents to the committee the insuperable difficulty of financing "major schemes." But in this is involved an erroneous method of regarding the matter. In severe cases of malaria justifying major schemes, when a town is impoverished by sickness and mortality, and, moreover—as such places must be—is a danger to the surrounding inhabited areas of the district in which it is situated, by reason of its wandering human malaria germ-bearers, it is sound political economy to require not solely the already impoverished locality but the district board, and, in exaggerated cases, the provincial government concerned, to afford financial aid, in part or whole. Nor need such a distribution of responsibility be regarded as financially impracticable if these principles be recognised. The borrowing powers of district boards remain practically unexploited, whilst the expenditure of funds in their charge is so erratic, and in such ill-considered proportions to the various requirements of the Acts they administer, that the best value is not obtained.

Average taxation for district board purposes does not exceed three half-pence per head *per annum*; but a single attack of fever (against several possible) *per annum* in the case of an adult, if the standard treatment by quinine approved by the Simla Conference be resorted to, would cause an unproductive expenditure of 10*d*. for this single drug, besides that due to extra luxuries during sickness, adjuvant medicines, and ceremonies, &c., irrespective of loss of labour. Yet, in the Punjab, where, during 1908, in round figures, there occurred 700,000 deaths from malarial fevers (giving a rate from this cause alone of 34·6 per mille of the population), the district boards concerned thought it proper to spend 24 per cent. of their incomes for education, against 1·5 per cent. for sanitation, including nothing for new water supplies. In connection with malarial fevers and "the drain upon the resources of India" they bring about, it is worth remembering that, during 1908, there were treated in the civil hospitals of India (where necessarily but a fraction of the population resort) a total of 5,211,851 cases of malarial fevers.

W. G. KING.

THE VOLUME OF THE KILOGRAMME OF WATER.

THE volume referred to below[1] contains three important memoirs relative to determinations which have been made during recent years by the Bureau International des Poids et Mesures, or under its auspices, on the volume of the kilogramme of water.

Since the fundamental work of Lefèvre-Gineau and Fabbroni, made towards the end of the eighteenth century, on which the prototype standard kilogramme was based, the question of the specific mass of water has been the subject of a number of inquiries in various countries. In spite of the critical and detailed examination to which these inquiries have been subjected, it is not easy to institute an exact comparison between the results, partly because the measures have been made and expressed in units of which the relation to the metric units is more or less uncertain, and partly because certain elements in the reductions and calculations have not been set out in sufficient detail.

A *résumé* of this work is given by M. Guillaume in the first of the three memoirs above referred to. From this account, in which the previous work has been carefully revised, and all corrections introduced, so far as known data would permit, it appears that the most probable values for the mass of a cubic decimetre of water deducible from the most important of the determinations subsequent to those of Lefèvre-Gineau and Fabbroni, are as follows:—

	kg.
1821. Shuckburgh and Kater ...	1·000475
1825. Svanberg, Berzelius, Akerman, and Cronstrand ...	1·000290
1831. Stampfer ...	0·999750
1841. Kupffer ...	0·999931
1893. Chaney ...	0·999850

The original work on which Lefèvre-Gineau and Fabbroni established the first standard kilogramme has also been minutely examined and discussed by several authorities, and M. Guillaume has subjected these revisions to a further scrutiny, from which it would appear that the following are the most probable values of the mass of the cubic decimetre of water:—

		kg.
According to the revision of	Broch (minimum)	0·999880
,, ,, ,,	Mendeléeff	0·999966
,, ,, ,,	Guillaume	0·999970

These numbers, it will be seen, differ notably among themselves, and even after due weight has been given to their relative probable value, it still remains uncertain in which direction the difference between the kilogramme as defined and as it actually is really lies.

The exactitude of these values ultimately depends upon the precision with which the linear and hence the cubical dimensions of bodies can be ascertained. Within recent years great increase in accuracy has been secured in such measurements by the application of the phenomena of optical interference as worked out by Fizeau and Michelson. In 1897 the late M. Macé de Lépinay ascertained the precise dimensions of a cube of quartz by this method and by means of it made a series of determinations of the mass of a kilogramme of water, and obtained the value 0·999959. In 1899, MM. Fabry and Perot made similar determinations by a modification of the method on the same cube of quartz, and found the value 0·999979.

These methods, with all the improvements which experience has suggested, have formed the basis of the series of determinations made by M. Chappuis, on

[1] "Travaux et Mémoires du Bureau International des Poids et Mesures." Tome xiv. (Paris: Gauthier-Villars, 1910.)

one hand, and by MM. Macé de Lépinay, Buisson, and René Benoît, on the other. That made use of by M. Guillaume consisted in ascertaining the measurements by mechanical contact—the old method, in fact, of Lefèvre-Gineau, modified by the refinements of modern metrology. In each of the methods the general problem was the same, namely, to determine by lineal measures referred to the prototype metre, the dimensions, and consequently the volume of a solid of definite geometrical form, say a cylinder or cube of brass, or glass, or quartz, of as perfect a form as possible, and then to ascertain the weight, referred to the prototype kilogramme, apparently lost by the solid when immersed in water. The two parts of this operation are of very unequal difficulty; that of ascertaining the dimensions is by far the more difficult. Thanks to the admirable equipment of the bureau, the hydrostatic weighings could be made with a very high degree of accuracy.

It is impossible within the space at disposal to enter into the details of manipulation or to explain the manner in which the experimental methods were carried out. For information on these points the memoirs themselves must be consulted. The final results, obtained after a careful revision of all the calculations, may be thus summarised:—

Method of Contact.

	cm.	Mass of a cubic decimetre of water (kg.)	Volume of a kilogramme of water (dm^3)	Weighted Mean
Bronze cylinder of	14	0·9999749	1·0000251	1·000029
,, ,,	12	0·9999655	1·0000345	
,, ,,	10	0·9999672	1·0000328	

Interferential Method by Reflexion.

	cm.	kg.	dm^3	
Cube of glass	4	0·9999713	1·0000287	1·000026
,,	5 1st measure	0·9999789	1·0000211	
	5 2nd ,,	0·9999784	1·0000216	
,,	5 reworked	0·9999731	1·0000269	
,,	6	0·9999696	1·0000304	
,,	5	0·9999731	1·0000269	

Interferential Method by Transmission.

	cm.	kg.	dm^3	
Cube of quartz	4	0·9999741	1·0000259	1·000027
,,	5	0·9999729	1·0000271	

With respect to the relative value of the methods of measurement, there can be little or no doubt in M. Benoît's opinion that those obtained by the method of optical interference are to be preferred to the mechanical method of contact. On the other hand, the older method has the advantage that bodies of larger volume can be employed with a corresponding diminution of error in other directions. The three results are, it will be seen, very close together. The final mean falls between 1·00027 and 1·00028, and is rather nearer the first than the second number.

Accepting the sixth decimal as the limit of accuracy, the ultimate result is that 1 *kilogramme of pure water, free from air, at 4°, and under normal pressure, measures* 1·000027 *cubic decimetre; or that the mass of* 1 *cubic decimetre of this water is* 0·999973 *kilogramme.*

The uncertainty of these numbers probably does not exceed 1 in the last figure, or about a milligramme on the kilogramme.

M. René Benoît, the director of the bureau, concludes the *résumé* of the three important memoirs which have led to this result which some general observations on its bearing upon the question of the relation of the actual value of the kilogramme to its original theoretical definition. He justly points out that the original standard kilogramme of Lefèvre-Gineau and Fabbroni was constructed with a perfection truly admirable, and altogether extraordinary when one considers the general state of science and the means at command in their epoch. Their kilogramme was in effect represented by the mass of a cube of water, the side of which measured not exactly 1 decimetre, but 1·000009 decimetre. Even if it be admitted that such a result could only have been obtained by a fortunate compensation of errors, it is certain that a like perfection can only be secured today by observers equipped with all the resources of modern metrology, working with the most scrupulous care, joined to a critical faculty of the highest order in the sifting and discussion of results.

He points out that whilst it might be possible to construct a new standard kilogramme in closer conformity with its definition, there would be little practical gain in so doing. The litre, the volume of a kilogramme of water, is in practical conformity with the cubic decimetre, not only for the needs of ordinary life but for by far the greater number of the requirements of science. Should any case need a higher degree of precision, there would be no difficulty in the application of a correction based upon the conclusions of the present work of the bureau. M. Benoit sees in the general result a proof of the wisdom of the decision of the International Metric Commission of 1872, not to disturb the original standards, but in constituting the international kilogramme as fundamental prototype simply to copy the old kilogramme of Lefèvre-Gineau and Fabbroni.

T. E. THORPE.

NOTES.

PROF. J. H. POYNTING, F.R.S., has been elected a foreign Fellow of the Reale Accademia dei Lincei.

BY the will of Mr. Thomas Lupton, solicitor to the Royal Institution, the institution will receive 10,000*l*. for general purposes.

M. ARMAND GAUTIER will be president of the Paris Academy of Sciences for 1911. M. Lippmann has been elected vice-president.

IT has been decided to establish a laboratory for researches in the chemistry of therapeutics in the Pasteur Institute in Paris. The laboratory will be directed by M. Ernest Fourneau.

ON Thursday next, December 29, Prof. Silvanus P. Thompson will commence the Christmas course of six juvenile lectures at the Royal Institution on "Sound, Musical and Non-musical."

THE Paris correspondent of the *Times* reports that Prof. Guignard, who has acted as director of the Paris School of Pharmacy for the last fifteen years, has resigned his appointment, and is succeeded by M. Henry Gautier, professor of mineral chemistry at the school.

THE Institution of Naval Architects, which was founded in 1860, has received an intimation from the Lord President of the Privy Council to the effect that the King has been pleased to approve of the grant to the institution of a Royal Charter of Incorporation.

A CORRESPONDENT of the *Daily Chronicle* states that a brilliant display of aurora borealis was witnessed at Hampstead on Monday, December 19, between 10.30 p.m. and 11 p.m. The display started in the north-north-west, and the streamers spread across the sky so far as the constellation of Orion.

We learn from *Science* that the Nichols gold medal of the American Chemical Society for the year 1909–10 has been awarded to Prof. M. A. Rosanoff, of Clark University, and his pupil, Mr. C. W. Easley, for their joint study of the partial vapour pressures of binary mixtures. The formal award will take place at the meeting of the New York Section on January 6, 1911.

Referring to the letter from Prof. W. A. Douglas Ridge on the tribo luminescence of uranium in Nature of December 15, Mr. H. A. Kent (The Poplars, Maidstone Road, Bounds Green, N.) writes to say that he noticed similar effects in 1904. He found by filling the tube containing metallic uranium with oxygen the brilliancy was much exhalted.

In continuation of the index volume printed twenty years ago, the Royal Society of Edinburgh has completed an index to the Transactions of the society issued during the years 1889–1908. The volume includes also an address by Sir Wm. Turner, K.C.B., F.R.S., president of the society, delivered at the opening of the new rooms on November 8, 1909.

A prize of 100,000 francs is to be awarded to the inventor of a practical apparatus which will make it possible to save the crews of wrecked submarines, enabling them to regain the surface uninjured. The French Minister of Marine is able to offer the prize, as he has received an anonymous gift from a French lady for the purpose. The conditions under which the prize will be awarded have been officially announced.

A memorial has been erected, says *Science*, at the National Bacteriological Institute in the City of Mexico to the late Prof. H. T. Ricketts, who at the time of his death was assistant professor of pathology in the University of Chicago and professor-elect of pathology in the University of Pennsylvania. His death was caused by typhus fever, which he contracted while conducting researches in this disease.

Among the many curious investigations carried out by means of instantaneous photography, not the least curious are those which Prof. A. M. Worthington, F.R.S., has devoted to the study of the effects produced by the fall of drops or solid spheres into water and other fluid. These investigations will be described and illustrated in this year's Christmas lectures at the Royal Society of Arts by Prof. Worthington.

In his recent annual report the Secretary of the United States points out that the attainment of the North Pole by Commander Peary has added to the honour and credit of the United States. The Secretary of State therefore recommends that Commander Peary should be given a commission by legislation as rear-admiral of the Corps of Civil Engineers of the U.S. Navy, to date from the day of his discovery, and that he be retired as from that date with the highest retired pay of that grade.

The death is reported, at the age of sixty-eight, of Dr. Charles Otis Whitman, for the last eighteen years head of the department of zoology and curator of the zoological museum at the University of Chicago. He had previously held appointments at the Imperial University of Japan, the Naples Zoological Station, Harvard University, the Allis Lake Laboratory, and Clark University. From 1888 to 1908 Dr. Whitman was director of the Marine Biological Laboratory at Woods Hole. He was editor of the *Journal of Morphology* and of the *Biological Bulletin*.

One of the most promising of American pathologists, Dr. Christian Archibald Herter, has died recently at the early age of forty-five. In 1890 he followed up his studies at Johns Hopkins University and Zurich by publishing a text-book on "The Diagnosis of Nervous Diseases." He then devoted himself especially to pathological chemistry, and held for several years the chair of that subject at the Bellevue Hospital Medical School, New York. Since 1903 he had been professor of pharmacology and therapeutics at the New York College of Physicians and Surgeons. Dr. Herter had carried out several scientific investigations for U.S. Government departments. He was treasurer to the Rockefeller Institute for Medical Research, and had himself created two lectureship foundations, one at Johns Hopkins University and the other at the Bellevue Medical School.

At the annual meeting of the Yorkshire Naturalists' Union, held at Middlesbrough on Saturday, December 17, a vigorous protest was made against the action of H.M. Stationery Office in reference to the increased prices which have now to be paid for hand-coloured editions of the maps of the geological department. It was pointed out that in withholding from the public cheap and easy access to the results of the Geological Survey, the objects of the Survey were in large measure defeated, and the cost of this department of the public service deprived of much of its justification. At the same meeting Dr. Alfred Harker was elected president for 1911, Mr. H. Culpin the hon. treasurer, and Mr. T. Sheppard hon. secretary.

The Eastern Telegraph Company report that an earthquake was felt at Zanzibar on December 14 at 11.40 a.m. Greenwich mean time. The shock must have been of great intensity over a wide area, for four of the company's cables between Zanzibar and Durban were broken at about the same time. The first tremors were recorded by the seismograph at Cardiff at about noon, the total duration of the movement there being about two hours.

Two slight earthquakes were felt throughout Glasgow on Wednesday evening, December 14, the first at 8.54 p.m. and the second shortly after ten. The first shock, which was strong enough to make windows rattle and to throw down some ornaments, lasted four or five seconds, and was accompanied by a loud rumbling noise. The area affected by it extends at least twenty-one miles east and west from Glasgow to Greenock, and ten miles north and south from Milngavie to Johnstone. The seismograph record at Paisley Observatory shows a disturbance, one-tenth of a millimetre in amplitude, at 8·54 p.m., and others of larger amplitude, but not connected with the Glasgow earthquakes, at 9.26 and 9.29 p.m., while a slight movement about 10 p.m. may have been caused by the second shock. The record obtained at the Royal Observatory, Blackford, Edinburgh, at about 10.30 p.m. had, of course, no connection with the Glasgow shocks.

In a communication published in the *Morning Post* of December 20 Prof. J. Milne, F.R.S., records the following series of earthquakes:—After a long period of rest we have had a succession of large earthquakes. On December 13 there was one on the West Coast of Africa, which broke several cables, and on December 14 one in Scotland. On December 16 one occurred so far off as New Guinea. On December 17, at 7.30 a.m., one reached us from a place so far distant as the West Indies. Next day, at 4 a.m., one came from Java, and in less than two hours, namely, at 5.49 a.m., there was another disturbance in the West Indies. There was a third at 4.50 p.m. With the exception of the disturbance in Scotland they were all very large, and shook quite half the world.

THE subject of the Neolithic age culture in Malta has been dealt with by Dr. Ashby and by Mr. Peek in the last issue of Papers of the British School at Rome. It has often been remarked that up to the present no cemetery of this race has been discovered. In a letter addressed to the *Times* of December 13 Mr. T. Zammit, curator of the Valetta Museum, announces that he has found on the road between Attard and Nobile an undoubted Neolithic interment. No flint implements were discovered with the remains, but the characteristic pottery and the iron ochre pigment in which the bones were soaked leave no doubt regarding the date of the interment. The discovery is most important, because on this evidence Malta falls into line with Sicily and Italy so far as the Neolithic culture is concerned.

AT a meeting of the executive committee of the British Science Guild, held on December 14, it was reported that a deputation on behalf of the Guild waited on December 2 upon the private secretary to the Prime Minister to represent the undesirability that Government should part with the site at Fosterdown which had been selected by the Solar Physics Committee three years ago as most desirable for the future site of the Solar Physics Observatory about to be vacated at South Kensington. This site, for some unexplained reason, had been put up by Government to be sold on December 13. The memorial protesting against this sale was signed by the surviving members of the Duke of Devonshire's Commission, past-presidents, and a large numbers of Fellows of the Royal Society, and of the British Science Guild. The Prime Minister was pleased to comply with great alacrity with the prayer of the memorial.

THE Franklin Institute recently awarded the Elliot Cresson gold medal, the highest in the gift of the institute, to several men of science. The secretary of the institute has favoured us with a detailed statement of the grounds of the award in each case "for distinguished leading and directive work," from which we extract the following particulars. The award was made to Dr. Edward Weston, Newark, N.J., for "electrical discovery and in the advancement of electrical application"; to Prof. Ernest Rutherford, F.R.S., for "the advancement of our knowledge of electrical theory"; to Sir Joseph J. Thomson, F.R.S., for "the advancement of our knowledge of the physical sciences"; to Sir Robert A. Hadfield, for "the advancement of our knowledge of metallurgical science"; to Dr. Harvey W. Wiley, chief chemist to the Department of Agriculture, Washington, D.C., for "work in the fields of agricultural and physiological chemistry"; to Mr. John Fritz, Bethlehem, Pa., for "work in the development of the iron and steel industries"; and to Dr. John A. Brashear, of Pittsburg, Pa., for "work in the production and perfection of instruments for astronomical research."

THE late Sir George S. Mackenzie, formerly Administrator of the Imperial British East African Company's Territories, left estate of the gross value of 104,004*l.* 19*s.* 6*d.*, of which the net personalty has been sworn at 99,647*l.* 17*s.* 9*d.* The residue of his property is bequeathed to his children in equal shares, and in the event of his leaving no children the following bequests are made:—(1) To the Ross and Cromarty County Committee 2000*l.* on trust to found two bursaries each of the value of 30*l.* per annum, to be known as the "Sir William Mackenzie and the Jessie Mackenzie Inchvannie Bursaries," to be tenable at the Scottish universities for students from Ross and Cromarty, and preferably from the National Schools, for the study of medicine, chemistry, engineering, or agriculture, or other branch of applied science. (2) To the Royal Geographical Society 1000*l.* to found a prize to take such form as the council of the society may see fit, and to be in commemoration of the great work done by the British East Africa Company in saving British East Africa for the British Empire. (3) To the president and council of the Royal College of Physicians and the Royal College of Surgeons, England, 30,000*l.* (subject to life interest of his two brothers), for the endowment of scientific research by students of ability and of registrable medical qualification, who may thus be able to devote their whole energies to such work, and be independent of ordinary practice. This bequest is made in the hope that the combined results of the systematic work of so many trained workers may prepare the way for a genius to come who will make great discoveries.

THE International Exhibition of Hygiene is to be held at Dresden in 1911. The object of this exhibition is in no sense commercial; it is being promoted for purely educational purposes, and it is intended to give hygienists of all nationalities an opportunity of learning what is being done in other countries in the direction of guarding the individual from the many dangers to health which exist, more particularly in our large industrial communities. It will bring home to the public what has been achieved by scientific research in the cause of hygiene, and it cannot fail to offer an impressive object-lesson to a large number of visitors from different countries of the importance, not only from the personal, but from the social and national point of view, of a due regard to the physical welfare of man. There is no doubt that the exhibition will be international in its widest sense, the Governments of far distant countries having already voted considerable sums of money for the proper display of what they have done and what they are doing in the domain of hygiene. To ensure this, the German Government has issued invitations to all the principal nations of the world to take an active part in this philanthropic scheme, and the invitation has been accepted by the very large majority of those to which it was extended. The only great country which stands aloof is Great Britain, a country which is universally regarded as occupying a foremost place among the nations in its appreciation and practical application of the requirements of sanitation. Although our Government, with its characteristic lack of appreciation of scientific work, does not seem disposed to take an official part in this international exhibition, it is to be hoped that money will be obtained from other sources in order to allow Great Britain to be represented adequately.

A CORRESPONDENT, Mr. George Boaq, writing from Aguilas, Murcia, Spain, directs attention to a method devised by Drs. Nasmith and Graham, of the Provincial Board of Health, Ottawa, for destroying typhoid and dysentery bacilli in water, and rendering it safe for drinking purposes. A level teaspoonful of chloride of lime is rubbed up in a cupful of water, the water being added little by little, so as to obtain a uniform emulsion. This is then diluted with three more cupfuls of water, and one teaspoonful of the dilution is added to two gallons of the water to be purified, mixing thoroughly, and the mixture is allowed to stand for at least ten minutes. The directions are somewhat rough and ready, but if the water tastes distinctly of chlorine sufficient chloride of lime has probably been added. A water containing much organic matter will require more chloride of lime than one containing little organic matter. For a water containing little organic matter one part of chloride of lime per million parts of water suffices, but for an impure water four or five parts may be required. If an excess of

chloride of lime be added the water becomes unpalatable, but the taste disappears on standing, particularly in bright sunshine, or may be destroyed by the addition of a dechlorinising agent such as bisulphite of soda. The efficiency of chlorine and chloride of lime for sterilising water has been amply demonstrated by many observers—Nesfield, Rideal, Thresh, Woodhead, and others.

In view of the recent scare of plague in the Eastern Counties, considerable interest attaches to a paper by Captain W. D. H. Stevenson (Scientific Memoirs by Officers of the Medical and Sanitary Departments, India, No. 38) giving a preliminary account of experiments on the killing of rats and rat-fleas by means of hydrocyanic acid, generated by the action of sulphuric acid on potassium cyanide. Fleas were killed very rapidly by the gas. In one experiment a mixture of 1 ounce of potassium cyanide, 2 ounces of sulphuric acid, and 4 ounces of water was placed in a small room of the capacity of about 346 cubic feet, and the door was then closed. After forty minutes the door was opened, and fifteen minutes later the room was entered; all the fleas left in different parts of the room were killed, even those placed inside four bags, three of blanket and one of cotton, but some of the fleas placed inside a box of clothes survived. Rats were found to require more gas and a longer exposure than fleas. On the other hand, plant-life appears to be uninjured by the gas, and cultures of bacteria were also unaffected by it. Dried grain is not made poisonous for food by the gas, nor are its powers of germination impaired in any way. Moist food-stuffs, however, such as water, milk, butter, and flesh, are said to absorb the poison, and should therefore be removed from a building during fumigation. The gas has no action on metals or fabrics.

That dorbeetles and their kindred are generally infested with mites in this country is a well-known fact, but it appears to be a comparatively new discovery that in Ceylon beetles of this group are likewise infested by minute species of flies. In the December number of the *Entomologist's Monthly Magazine* Mr. J. E. Collin describes a new species of small hairy flies of the genus Limosina taken from a coprophagous beetle in Ceylon. The flies were found clinging to the under surface of the beetle, and, instead of attempting to fly away, allowed themselves to be dropped into a collecting tube without change of position.

In *British Birds* for December it is stated that about 7900 birds were ringed in this country during the year, Messrs. Smalley and Robinson having marked no fewer than 2313 out of this number. In the editor's opinion it is at present too early to decide whether the results will repay the trouble and expense involved in marking. Its chief results will relate to the movements of individual birds, and it is urged that special attention should be paid to the recapture of the smaller marked birds by the editor's correspondents, most of those which have been taken having fallen into the hands of persons unacquainted with the scheme. The costs of the inquiry during last year considerably exceeded the funds at the disposal of its promoter, and if the scheme is to be continued next season it can only be by the aid of special subscriptions.

In the Proceedings of the United States National Museum (vol. xxxix., 1910, pp. 37–91) Mr. R. E. Snodgrass, whose treatise on the structure of the honey-bee was noticed in Nature of December 8 (p. 169), publishes an important memoir on the thorax of the Hymenoptera. In this paper the modification and elaboration of the thoracic skeleton in the various families of the order are described in detail, and illustrated by nineteen text-figures and fifteen plates. The author finds no support for Verhoeff's theory that each thoracic segment is a complex of three primitive somites, but prefers to regard the serially arranged sclerites of the mesonotum and metanotum—so fully shown by many Hymenoptera—as evidence of specialisation.

In vol. v., No. 3, of the *Philippine Journal of Science* Mr. L. E. Griffin publishes additional information with regard to the pearl-fishery, dealing in this instance with the products obtained off Bantayan, an island lying between the northern ends of Negros and Cebu, at the head of the Tañon channel. In May and June, and again in November and December, the water is usually so still and clear that the bottom can be seen to a depth of eight fathoms, and it is at these seasons that the natives look for oysters. In place of forming banks, these occur sporadically, and were it not for the shortness of the season there is little doubt they would long ago have been exterminated. The shells, although of relatively small size, are of excellent quality, but they are chiefly valuable on account of the large percentage of pearls they yield and their fine quality. During the present year one pearl of the value of 80*l.* was collected, while others worth from 20*l.* to 40*l.* each were obtained. The total annual value of the fishery is about 900*l.*

A survey of the vegetation on the Kasatzkisch steppe, near Kursk, is contributed by Mr. V. Alechin to the botanical section (part ii.) of *Travaux de la Société des Naturalistes de St. Pétersbourg* (vol. xli.). The main feature is the great predominance of dicotyledons, although *Carex humilis* takes an important part in the ground cover. The author concludes that the steppes existed previously to the wooded areas, and that they have been but little modified by human agency.

The suitability of bamboos and lalang, or cogon grass, for making paper pulp is considered by Mr. G. F. Richmond in an article on Philippine fibres published in the *Philippine Journal of Science* (Section A, vol. v., No. 4). Proceeding upon evidence furnished by other investigators and by laboratory experiments, the author takes a favourable view of the prospects of a local soda pulp mill for treating bamboos, and supplies an estimate of the probable cost. Also it is stated that a supply of raw material and the necessary fresh water could be obtained in several localities.

Bud-rot disease of palms has been notified within recent years from the West Indies, Ceylon, India, and the Philippine Islands, but in most cases the cause of the disease has not been definitely established. Dr. E. J. Butler, who has conducted the investigations in India, where palmyra palms are chiefly attacked, attributes the disease there to a Pythium, deriving his conclusions from the inoculation of healthy palms. The source of the disease in the other countries, where cocoanut palms are infested, is probably different. Dr. Butler has embodied his latest researches, together with a general account of the distribution and remedial measures adopted, in the botanical series (vol. iii., No. 5) of the Memoirs of the Department of Agriculture in India. Two spore forms are recognised; in the ordinary case the contents of a sporangium break up into zoospores, but in hot, dry weather a resting variety of conidium is more commonly found.

THE Journal of the Royal Society of Arts for December 9 contains a paper delivered to the society by Mr. A. Montgomery, State Mining Engineer of Western Australia, on the progress and prospects of mining in Western Australia. Mr. Montgomery states that the metallic minerals occur in very old igneous and sedimentary rocks, which are almost certainly pre-Cambrian. His conclusion is that Western Australia owes the present shape of its surface largely to submergence beneath the sea within post-Tertiary times. The paper was accompanied by an exhaustive statistical appendix, from which we find that for the quinquennium 1903–7 the world's production of gold was 76,000,000*l*., of which the Commonwealth of Australia contributed 20 per cent. and Western Australia $10\frac{1}{2}$ per cent. For the same quinquennium the gold produced has been more than 96 per cent. of the total mineral production, and the mineral export from Western Australia has been 80 per cent. of the total for all the exports from the colony. The value of gold produced per man employed has been more than 400*l*. during the years 1908–9. In regard to the help afforded by the Government to the mining industry, attention is directed to the extensive development of the railway lines and of the systems of water supply; water is sold to the mines at from 4*s*. 9*d*. to 8*s*. 6*d*. per 1000 gallons.

THE November number of *Petermann's Mitteilungen* contains an interesting map of Siberia taken from one published by the Russian Academy of Sciences, which shows the distribution of places where remains of the mammoth and rhinoceros have been found. Most of them lie within the Arctic circle, but one of the former and three of the latter sites lie further to the south.

AN event of much interest in cartography is the completion, after about thirty years' work, of the 1 : 100,000 map of Germany in 675 sheets. A full account of these maps and the various stages in their development and their production is given by Colonel v. Zglinicki, chief of the cartographic section of the Prussian Survey, in a recent number (No. 9) of the *Zeitschrift der Gesellschaft für Erdkunde*.

THE determination of the international boundaries in Africa proceeds apace, and in Heft 4 of the current volume of *Mitteilungen aus den deutschen Schutzgebieten* are published the latitudes and longitudes which were determined in 1905–7 along the boundary which divides the Cameroons from the French Congo. Neither the time available nor the funds at disposal sufficed to carry out a chain of geodetic triangulation along the boundary, so that it was necessary to rely on astronomical observations alone. Latitudes were determined by circummeridian altitudes of north and south stars, and longitudes by lunar observations, and in three cases only by star occultations. Observations made at the observatories of Greenwich, Paris, and Göttingen were utilised to furnish the final corrections, the uncertainty of the results being ± 2 to ± 5 seconds.

UNDER the title of "The Burial of Olympia," Prof. Ellsworth Huntington in the *Geographical Journal* for December applies the theories advocated in his work "The Pulse of Asia" to the problem of the decadence of Greek civilisation. This is often attributed to deforestation; but from evidence collected in America by Prof. Moore, chief of the United States Weather Bureau, he denies that this can have played an important part in the ruin of the natural resources of Greece. He assumes that pulsatory changes of climate, such as the rapid desiccation of parts of Asia, may have occurred in Greece in the millenium preceding 600 A.D. To these he attributes many of the world's greatest movements of population, such as the attacks of the barbarians on southern Europe, the invasions of Genghis Khan and Tamerlane, and he connects with these the spread of malaria due to the introduction of the mosquito, for which Greece now became a fitting habitat. In the instructive discussion which followed, these views were criticised by Prof. Myres, Dr. Hogarth, Dr. Stein, Prof. Gregory, and others, most of whom, while admitting the novelty and interest of Prof. Huntington's suggestions, desired further evidence. This may perhaps be gained from Prof. Huntington's recent work in the American deserts; but until the question of North Africa is settled the general problem cannot be finally decided.

IN the *Popular Science Monthly* for December Prof. S. W. Williston discusses the birthplace of man in the light of the palæontological record. The evidence, he suggests, points to the conclusion that it was in India and its borderlands that the chief domesticated animals were specialised—the genus Bos in the Indian Lower Pliocene, the swine, horse, elephant, and the cat tribe; among birds, the ostrich, jungle-fowl, peacock, and grey goose. Man may have been developed in this region during the Late Miocene or Early Pliocene periods. He believes that within a very few years the discovery of indubitable links in man's ancestry will be made in Central Asia, China, or North India, there being no other region to which the palæontologist looks with more eager expectation for the solution of many profound problems in the phylogenetics and migrations of mammalian life.

THE Transactions of the Leicester Literary and Philosophical Society for 1910 contain two geological papers of interest. Mr. F. Cresswell deals with the frequently discussed question of the origin of the English Triassic strata, with special reference to the Keuper marls. He suggests that the grey bands represent periods of moister climate, when minute organisms reduced the peroxide of iron to protoxide. While regarding the floor on which the English Trias was deposited as a rocky tableland, he falls into a very common error by stating that the Libyan Desert differs from this, being "a uniform sandy plain." Mr. Cresswell fully supports the view that desert conditions prevailed in Triassic times in England, and urges that the Keuper marls are formed of particles worn from igneous and metamorphic rocks by "weathering with a very limited amount of water." Mr. J. McKenzie Newton contributes an essay on the crystallisation of igneous rocks.

IN the Bulletin of the Central Meteorological Observatory of Japan (No. 5, 1910) Mr. T. Okada discusses in great detail the rainy season in Japan, which usually extends from about the middle of June to the middle of July, and is the most important period for the cultivation of rice. To make the investigation more complete, five-day means are given for the whole year for a large number of stations in Japan and adjacent districts, with charts and a short discussion of each of the principal elements. The figures show that in Japan proper the rainfall reaches a maximum at the end of June or in the first decade of July; it then falls to a minimum in August, and again increases to a maximum in September or October. The rainfall of the season in question is chiefly caused by cyclonic disturbances from the Yangtse Valley and Formosa, and is not a simple monsoon rainfall. The period is characterised by continued cloudy weather, large relative humidity, comparatively high temperature, small wind-velocity, and more or less rainfall every day. The discussion extends to eighty-two quarto pages.

The use of the Clark and Weston cells as standards of electromotive force has necessitated a close study of the properties of cadmium and zinc amalgams, and numerous valuable papers on this subject have issued from the van 't Hoff laboratory at Utrecht. In the current number of the *Zeitschrift für physikalische Chemie* (December 2) is a further contribution from this laboratory by Ernst Cohen and P. J. H. van Ginneken, dealing with the properties of zinc amalgam as affecting the Clark cell. The authors conclude that the formula in current use representing the relation between the E.M.F. and the temperature of the Clark cell is not trustworthy, and should not be employed in accurate measurements. It is further shown that for exact work the Clark cell must be used at temperatures between 20° C. and 38° C.

The Department of Mines, Canada, has sent us a copy of the report of analyses of ores, fuels, &c., made in the chemical laboratories of the Geological Survey during 1906 and 1907, and of the Mines Branch of the Department of Mines in 1906, 1907, and 1908. With the exception of twenty-seven rock analyses, the work done is chiefly of practical interest, analyses being given of numerous coals, lignites, peats, and ores of iron, copper, and chromium. The results of seventy-seven gold and silver assays show the wide distribution of the precious metals in Canada. In an appendix a description is given of the commercial methods and apparatus used for the analysis of oil-shales.

Messrs. Whitcombe and Tombs, Ltd., will publish shortly a fully illustrated work on "Australian Plants" suitable for gardens, parks, timber reserves, &c., by Mr. W. B. Guilfoyle.

OUR ASTRONOMICAL COLUMN.

A Projection on Saturn's Outer Ring.—During the total eclipse of the moon on November 16 M. Jonckheere directed the 35-cm. equatorial of the Hem Observatory to Saturn, and found a bright projection extending outwards from the eastern extremity of the exterior ring. The projection was best seen with low powers (100 and 200), and its intensity decreased gradually, going from the outer edge of ring A on to the background of the sky. On November 20 and 24 the same projection was seen with difficulty (*Astronomische Nachrichten*, No. 4461).

Discovery of Another Nova, Sagittarii No. 3.—In a note appearing in No. 4459 of the *Astronomische Nachrichten* Prof. E. C. Pickering states that Miss Cannon has found that a new star appeared in the constellation Sagittarius on August 10, 1899. A photograph taken on August 9, although showing stars of magnitude 11·5 in the immediate neighbourhood of the nova, shows no trace of it, yet on August 10 it is a conspicuous object of magnitude 8·5. While the outburst was so sudden, the decline, as is common with such objects, was very rapid, for the light faded from 8·6 on August 25 to 10·5 on October 13, 1899; the decrease after that date was more gradual. The nova is not shown on any photograph taken after October, 1901, when its magnitude was about 13·0. The position of this object was R.A. = 18h. 12·2m., dec. = −25° 14′ (1875·0); this is about 10m. west of λ Sagittarii and 20m. east of Nova Sagittarii No. 2.

Faye's Comet.—Having identified Cerulli's comet with Faye's short-period comet, M. G. Fayet has investigated the orbit with the idea of obtaining closer agreement with Dr. Strömgren's elements. Employing three observations, made between November 10 and 22, he calculated the value for the mean motion and obtained two sets of elements, which, however, were not altogether satisfactory. Then on November 30 he secured a further observation, and this enabled him to apply the method of the variation of geocentric distances and to calculate other systems, the fifth of which agrees very nearly with Dr. Strömgren's elements for 1903, except that the mean motion is 486·792″ instead of 480·16″; they also give a close agreement with the observations. From the best system obtained, which may, however, yet be improved, M. Fayet has calculated an ephemeris giving daily positions up to January 30, 1911 (*Astronomische Nachrichten*, No. 4461).

New Experimental Demonstration of the Earth's Rotation.—An interesting description of an experiment devised by Father Hagen to demonstrate the rotation of the earth is described by M. B. Latour in No. 1346 of *Cosmos* (November 12). Father Hagen's apparatus consists of a balanced beam of wood, 9 metres long, which has a bifilar suspension, and to which is attached heavy masses movable in the horizontal plane towards and away from the suspension. In the modified experiment these masses each consist of 80 kilograms of lead mounted in small waggons, which can be automatically released by the fusion of a leaden wire. When released the waggons run towards the centre, the moment of inertia of the beam is modified, and it swings relatively to the earth; the motion is shown by a mirror attached to the suspension and reflecting a beam of light on to a scale fixed on the wall of the circular room wherein the apparatus is installed. When the chariots are made to run from the centre to the extremities the swing of the beam is in the opposite direction and about half the amount. With Father Hagen's apparatus, mounted in the massive tower which carries the astrographic equatorial at the Vatican Observatory, the mean of twenty experiments gave a value for the earth's rotation very near the theoretical value at Rome.

Investigation of the Orbit of Wolf's Comet, 1898–1911.—In No. 4460 of the *Astronomische Nachrichten* M. M. Kamensky gives in brief the results of an elaborate investigation he has made of the movements of Wolf's comet during the period 1898–1911. This is the well-known short-period (6·7 years) comet discovered by Wolf at Heidelberg on September 17, 1884, and independently by Copeland with the spectroscope on September 22; it was reobserved in 1891 and 1898, but was not seen in 1904–5. The orbit was completely transformed by Jupiter in 1875, but the slight differences between the observed and calculated places in 1898 indicate that it is now a permanent member of our system.

M. Kamensky first investigated the motion during the period 1898 August 22 to 1904 June 12, taking into account the perturbations of the earth, Mars, Jupiter, Saturn, and these are published in full in No. 15 (1910) of the *Bulletin de l'Academie Impériale des Sciences de St. Pétersbourg*. He then carried the investigation forward to March 28, 1911, and publishes the full tables in No. 16 of the Bulletin; he also gives elements showing the severe perturbation by Jupiter in 1875, and states that extraordinary changes may again take place at a near approach in the latter part of 1922.

According to the final elements, the next perihelion passage should occur on February 24, 1912, and in Bulletin No. 16 M. Kamensky gives an ephemeris for the period 1911 January 3 to October 14; for the latter date the estimated magnitude is 12·2.

The Light Changes of Forty-nine Variable Stars.—In the fourteenth issue of the *Bulletin International*, published by the Cracow Academy of Sciences, Dr. L. Pračka discusses the light changes of forty-nine variable stars. The observations were made at the Bamberg Observatory during 1905–9, and each star is discussed at length. A summary of the results is given in handy tabular form at the end of the paper showing the elements, the magnitudes and colour, and the form of the light-curve for each object.

THE PHYSICAL SOCIETY'S EXHIBITION.

On Tuesday, December 20, the Physical Society of London held its annual exhibition of physical apparatus, and the occasion was marked by some interesting experimental lectures. Prof. J. A. Fleming, F.R.S., chose for his subject some improvements in transmitters and receivers for wireless telegraphy, and referred first to his well-known oscillation valve, consisting of a glow lamp in which a metal plate of some convenient form is

fixed. When the filament (which in the latest form is of tungsten) is glowing, a current will flow if an E.M.F. is applied between the negative terminal of the filament and the metal plate; the current can flow from the filament to the plate, but not in the reverse direction, and thus rectification results. Owing to the upward trend of the conductivity curve a much higher sensibility is obtained by applying a certain constant E.M.F. on which that due to the oscillations is superimposed. Passing to the question of the spark, the lecturer reproduced some interesting records showing how greatly the secondary current is increased when the spark gap is subjected to an air blast. Finally, Prof. Fleming showed his new form of spark discharger. This is of the Wien "quenched-spark" type, and consists of two heavy steel circular discs, one above the other, very perfectly surfaced and with an air gap of $\frac{1}{4}$ mm. between them. The lower disc is stationary and the upper one is rotated. The discs are placed in oil, and as there is a hole in the lower disc there is a continual circulation of oil. The discharger is found to give very satisfactory and uniform results, and has been used for measuring losses in condensers.

Mr. R. W. Paul gave several demonstrations of kinematograph diagrams. One series, due to Prof. R. W. Wood, illustrated sound waves; but certainly the most effective films were those due to Prof. S. P. Thompson, F.R.S., showing the movement of lines of force as a keeper approaches a magnet, the starting of a current in a solenoid, the rotation of a dynamo armature (in section), and other similar phenomena. These must have appealed strongly to teachers of magnetism.

As regards the apparatus exhibited, it may be said that there were many interesting new instruments, though perhaps nothing very striking, and there was much excellence in many exhibits that were not essentially novel. Thus in optical work A. Hilger, Ltd., gave an excellent display of spectroscopic instruments and a beautiful demonstration of anomalous dispersion. R. and J. Beck showed a small spectroscope giving large dispersion and with a sine motion so as to give wave-lengths direct. Carl Zeiss, as usual, gave an interesting exhibit, including the movement of gold particles (stated to be about 6 $\mu\mu$ in size) in colloidal solution, a special "cardioid" condenser being used, consisting of two lenses combined, and so shaped that a top illumination is secured for a dark ground, although the beam of light comes from below the centre of the stage. Messrs. E. Leitz showed a large projection apparatus giving excellent definition.

Photometric apparatus was not so much in evidence as on former occasions, but R. and J. Beck, and also Everett, Edgcumbe and Co., showed very small portable photometers for measuring surface brightness and illumination. As an exhibit of general interest may be mentioned that of Strange and Graham illustrating flapping flight. Two wings are worked by "Vilcar" mechanism, and a distinct upward pull is noticeable, apparently due to the upward path of the wing differing from that on the downward stroke.

The largest number of exhibits, as usual, were electrical. Several interesting thermo-electric exhibits were shown by the Cambridge Scientific Instrument Co., among which may be mentioned an arrangement for keeping the cold junction of a clinical recording thermometer at a constant temperature. This junction is covered by a small Dewar vacuum vessel, and is surrounded by a heating coil, which comes into action as soon as the temperature falls below a certain value; by this means the temperature of this junction is maintained constant to 0·1° C. This firm also showed compensating leads consisting of copper and copper-nickel alloy; these are run in series with the pyrometer, and, being thermo-electrically equal to the platinum/platinum-iridium couple, they transfer the cold junction of the pyrometer to the galvanometer, thus securing less variation in temperature of the cold junction. An arrangement whereby a constant E.M.F. is obtained for applying to a pyrometer so as to secure a false zero was also shown, and we noticed a convenient piece of apparatus for tracing recalescence curves; also an improved form of C. T. R. Wilson's tilting gold-leaf electroscope. A new form of radiation pyrometer which does not require focussing was shown by the Foster Instrument Co., who also exhibited some special thermo-junction alloys. H. Tinsley and Co. showed a set of instruments largely due to Dr. C. V. Drysdale, and some interesting vector diagrams of alternating magnetic flux in an iron wire, obtained by Drysdale's alternate-current potentiometer. This firm also showed a simple and strong form of vibration galvanometer based on the familiar Kelvin galvanometer; a heavy permanent magnet is provided for the control, and the tuning is effected (without affecting the zero) by magnetically shunting this magnet to the desired extent. The alternating current traverses a small coil, which can be easily changed, and the makers state that the instrument can be used for alternating pressures down to 1/100th micro-volt. R. W. Paul exhibited a well-designed new type of decade standard resistance box with switch contacts, the case being filled with oil, and we noticed some new transforming apparatus by Leslie Miller and by Muirhead and Co. Since there were thirty-five exhibitors, we need scarcely say that there was a good deal to be seen, but in the above notes we have only been able to refer very briefly to a few of the more interesting items.

INVESTIGATIONS ON WHEAT IN INDIA.[1]

THE importance of the wheat crop in India is not always realised at home. Until the last few years we received more wheat from India than from Canada or Australia—sometimes more than from both countries put together. At the present time wheat represents some 7 per cent. of the total value of merchandise exported from India, but the amount exported is only about one-tenth of the total production, the remaining nine-tenths being consumed in the country itself. When an industry has reached such great dimensions without excessive nursing it is clear that those engaged in it have consciously or unconsciously adopted tolerably satisfactory methods of working, and any attempt on the part of an outsider to effect improvements must be developed cautiously. When in 1906 the Indian Board of Agriculture decided to take up the matter seriously, they entrusted the work to Mr. and Mrs. Howard, and subsequent events have amply justified the wisdom of their choice. Several important papers have been issued, and finally a volume, "Wheat in India," in which the authors summarise the present position of the problem and indicate the lines on which advancement may be hoped for.

Mr. and Mrs. Howard devote the first half-dozen chapters of their volume to a general sketch of wheat-growing in India. Wheat is fairly widely distributed over the country, but the areas where it is really important all lie to the north or on the Central Plateau above the Ghats. In the north-west a great deal of the wheat is irrigated; the Punjab is especially well suited to canal irrigation by reason of its never-failing snow-fed rivers and its level tracts of land, but recourse is also had to irrigation by wells. On the other hand, in the Central Provinces, Bengal, and Bombay, only a small area is artificially watered.

In general, the soil is thoroughly well ploughed or scarified during the monsoon and previous to sowing, as many as fourteen ploughings being sometimes given. A good deal of manure is applied in the northern districts, but usually to the maize crop preceding the wheat; in the Central Provinces the monsoon (*kharif*) crop of rice, which precedes wheat, is slightly manured, but in Bombay the irrigated wheat itself is manured. Harvest begins in the Central Provinces in March, elsewhere in April, May, and even the end of June in the frontier districts. The wheat for export has to be got to Karachi for shipment as soon as possible, or it rapidly deteriorates, and is attacked by moths and weevils. In the rush the railway resources are heavily taxed, just as they are in Canada; the Indian case is, indeed, the worse, as there is no elevator system.

These preliminary chapters are illustrated by maps,

[1] "The Milling and Baking Qualities of Indian Wheat." No. 2. By Albert Howard and Gabrielle L. C. Howard.
"The Influence of Environment on the Milling and Baking Qualities of Wheat in India." By Albert Howard, H. M. Leake and Gabrielle L. C. Howard. (Pusa: Agricultural Research Institute.)
"Wheat in India, its Production, Varieties, and Improvements." By Albert Howard and Gabrielle L. C. Howard. Pp. ix+288. (Calcutta: Thacker, Spink and Co. London: W. Thacker and Co., n.d.)

quotations and statistics, and give an illuminating account of wheat-growing in India.

Passing on to a discussion of experimental work, the authors point out that manurial trials on orthodox lines are of purely academic interest in India. It was no doubt an excellent thing to make them, but their value is limited by the fact that the cultivator cannot usually buy the necessary manures. It is much more to the point to make cultivation trials, seeing that labour is very cheap and the labourer realises the necessity for working the land. But here again intelligent planning is necessary; if the trials are to serve as demonstrations for the native they must be made with implements he can afford to buy and learn to handle, and which the village blacksmith can repair. A summary is given of the well-known Cawnpore experiments, which show that the nitrogen supply is the limiting factor in normal conditions of moisture and temperature obtaining there. At Nagpur nitrogen was also the most important factor, but the water supply was in this case near the limit. The Punjab irrigation experiments, said to be the best of their kind in India, were made to ascertain the best quantity of water and the best number of waterings. It was found that the native was, like many other irrigation farmers, taking too much water, so that the area under treatment was needlessly curtailed, and the revenue suffered loss. But the authors further point out that over-watering gives rise to mottled grain and to samples uneven in texture, and therefore of low value. This loss in value, of course, falls on the cultivator himself, and if it could be brought home to him would, no doubt, induce him to take less water.

The authors then discuss the factors adversely affecting the production of wheat in India. In order of merit these are climatic extremes, fungi, insects, and vermin. Of the diseases, rusts are the most important, transcending in effect all other diseases put together. The only trustworthy remedy at present known is to grow rust-resisting varieties. Introduction of such wheats of high repute from abroad proved to be useless; wheats resistant in Australia succumbed badly in India, and, indeed, were more susceptible than the indigenous kinds, besides ripening too late. It therefore became necessary to raise new varieties from Indian wheats, and this work was begun by the authors in 1905. The first step was to take stock of the native sorts. An ordinary Indian wheat-field contains a mixture of several sub-varieties, which had to be isolated. These in turn comprise several types, agriculturally distinct, though botanically identical, and within each type individual variations occur. Selection was carried on, not on the old mass-selection lines, but by isolating single plants and studying their progeny in succeeding generations. The separation of forms and of pure lines has been successfully accomplished, and already several wheats have been obtained which are of much greater value than the mixtures at present in cultivation. Indeed, five of the Pusa selections have been shown by milling and baking tests to be in the same class with the Canadian spring wheats, the strongest and most valuable on the market. When the botanical survey was well on to completion it was possible to hybridise. This work is now in hand, and it is to be hoped that Mr. and Mrs. Howard will be able to carry the hybridisation on for the necessary length of time, so that the full benefit of their survey and selection work may be obtained.

A list of the botanical varieties of wheat found in India is then given, and for certain provinces the agricultural varieties as well. This survey is still in progress.

Throughout the book and the papers which the authors have issued the various wheat problems of India are handled in a masterly way. The record of work done reflects the highest credit on the authors, and is full of promise for the future of Indian agriculture.

THE REDUCTION OF ROLLING IN SHIPS.

REFERENCE is made in *Engineering* for December 16 to a paper by Mr. H. Frahm at the November meeting of the Schiffbautechnische Gesellschaft, in which the author describes his apparatus for reduction of rolling in ships. In this apparatus two water tanks are disposed on opposite sides of the centre line of the ship near the shell, and are connected below by a water conduit and above by an air conduit; a throttle valve is inserted in the latter. The water tanks are filled partly with water, which may oscillate in the closed circuit formed by the conduits. If the throttle valve is closed oscillation is practically prevented; with the valve full open the oscillations are unobstructed, excepting that free waves cannot arise.

The principle on which the device is based is that a series of wave-impulses will cause the ship to oscillate about its longitudinal axis; these oscillations will become pronounced when the period of the waves agrees with that of the natural vibration of the ship. These differ in phase by 90°, *i.e.* the maximum deflection of the ship from the vertical will occur a quarter period after the wave has been at its maximum inclination to the ship. The same applies to the oscillations of the ship and to those of the water column in the tanks, which rises and falls so that the two oscillation periods are equal, provided the water has the proper mass. In this case the oscillations of the water column will lag a quarter period behind those of the ship, and hence half a period behind the period of the waves, and the two turning moments acting on the ship will therefore oppose one another. This is an application of the principle of resonance.

Mr. Frahm's apparatus is beyond the mere experimental stage. The oil-tank boat W83 of the German Navy, 446 tons displacement, is a very stiff boat, with a high natural vibration period of 10·75 per minute. In dock the deflections from the perpendicular were reduced from 10° to 2° by twelve oscillations when the tanks were cut out, and by two oscillations with the tanks in action. At sea the amplitude of rolling was diminished to one-third. Two steamers of the Hamburg-America Line—the *Ypirango* and *Corcovado*—of 12,600 tons displacement, have been fitted with the anti-rolling tanks. The former was a notorious roller. Both are now regarded as steady boats; the tanks reduce rolling 11° (on either side) to 2½° maximum. Messrs. Blohm and Voss are designing anti-rolling tanks for the new passenger steamer of 55,000 tons which they are now building for the Hamburg-America Line. The paper in itself is very interesting, and is doubly so in view of statements made recently in the case of the loss of the British steamer *Waratah*.

ARGENTINE METEOROLOGICAL RESEARCH.[1]

THE services rendered to meteorology by Dr. W. S. Bruce in founding the meteorological observatory at Scotia Bay, South Orkneys, in 1903, are brought into forcible evidence by the publication of successive years' observations. Through the exertions of Dr. Escalante, Minister of Agriculture, and the enthusiasm of Mr. W. G. Davis, the Argentine Meteorological Office was enabled to take over the observatory from the Scottish National Antarctic Expedition, and has maintained it ever since. It must be remembered that this is the only permanent meteorological observatory in Antarctic regions. The observations for 1904, with an introduction by Mr. R. C. Mossman, are now published, though the title-page is dated 1905. The observations of following years seem not yet to have appeared, but they are briefly summarised in a most interesting and useful outline by Mr. W. G. Davis on the climate of the Argentine Republic. It may be mentioned, also, that a discussion by Mr. Mossman of each successive year's observations has appeared year by year in the *Scottish Geographical Magazine*. The tardy appearance of the 1904 volume detracts somewhat from its interest in view of our knowledge of the six later years, but we understand that circumstances beyond the control of the Meteorological Office alone delayed the publication.

Previous to the expedition of the *Scotia* it was supposed that, from their latitude, the South Orkneys would enjoy an oceanic climate. Actually, however, these conditions only obtain for four months, while for the rest of the year the conditions are continental. In exceptional years either of these states of climate may be prolonged at the expense of the other. The climate largely depends on the distribution of ice in the Weddell Sea. The average mean

[1] Anales de la Oficina Meteorológica Argentina. Tomo xvi., Observaciones de las Islas Orcadas en el Año 1904. Text in both Spanish and English. (Buenos Aires, 1905.)
"Climate of the Argentine Republic." By W. G. Davis. (Buenos Aires: Department of Agriculture, 1910.)

monthly temperature for five years (1903–8) varies from 9·68° F. in July to 32·54° in January, while the absolute range in the same period was 88°. The temperature variability of the seasons brings out the tendency to a winter continental and a summer oceanic climate. These values are (1904):—spring, 5·1°; summer, 1·3°; autumn, 5·4°; winter, 9·1°. The year 1904 had a mean annual temperature of 22·4°, which is 0·96° below the average mean of the five years 1903–8.

The wind directions, which were taken from the movements of the lower clouds, since the high land to the west of the observatory tended to deflect many winds, show a prevalence of north-westerly winds. Subsequent years' observations give west and south-west winds as the most frequent, which seems to show that the readings of 1904 give too high a value to north-west winds. Undoubtedly the position of Omond House is such that west and south-west winds would tend to be below what would be recorded in an unexceptional situation. In fact, on further consideration, Mr. Mossman has, we understand, come to the conclusion that the wind directions of 1904 are not wholly trustworthy. East, and especially north-east, winds are conspicuously rare, and the percentage wind frequency for each season does not materially differ from that of the year. The temperatures associated with these winds are of great interest, but unfortunately in Mr. Davis's five years' summary no thermal wind-roses are given. Very probably the high temperatures associated with some of these apparent westerly winds is partly due to Föhn effects, since in May, 1903, that is, in midwinter, an undoubted Föhn wind raised the temperature at the site of the observatory to 46°, which was only 1° lower than the absolute maximum of the year.

Associated with these prevailing west and south-west winds, which were also experienced by Dr. Nordenskjöld at Snow Hill in 1902–3, there exists a low-pressure area in the Weddell Sea, furthest south in autumn and most northerly in winter, but with a centre normally about 66° S. and 30° to 35° W. The continental origin of these prevailing winds accounts largely for the low temperatures of the South Orkneys compared with their latitude. The thermal gradient on the east of Graham Land is steep, and this fact, in relation to the southward bending of the isotherms about 40° W., is strong evidence for the existence of the northward projection of Antarctica south of the South Orkneys to about the Circle. Moreover, on no other grounds is it possible to account for the very low temperatures that occur from time to time at Scotia Bay with southerly and south-easterly winds.

NATIVE WORKING OF COAL AND IRON IN CHINA.

AN interesting illustrated article on the native working of coal and iron in the province of Shansi, China, appears in *Engineering* for December 2. In the Ping Ting Chau districts the iron ore is of excellent quality. The methods of extraction are decidedly primitive; in the old workings the ground is often found honeycombed with small shafts, seldom more than 14 inches in diameter, and usually just large enough to allow a man to go down. The tools used consist of a native pick, a cast-iron hammer, a wedge, and a sort of basket-shovel, the ore being raised in the basket by a small wooden winch. The climate is healthy, but work under such conditions is sure to produce disease, and consumption is very prevalent. During the summer the mines are shut down, and all the men become farmers until the close of the harvest season. The southern district specialises in wrought-iron goods, for example, spades, picks, nails, wrought-iron bars, and general ironwork; the northern district produces the larger and rougher classes of goods, such as cast-iron pans and sections of tyres for cart-wheels. Reduction of the ore is conducted in roasting-kilns; the broken-up ore is mixed with anthracite and charged into clay crucibles, which are heated in the kilns for about four days. The iron residue is then treated in a foundry, where it is broken up and remelted in crucibles for the production of cast iron, or, if wrought iron is being produced, by melting in a crude furnace, hammering, and puddling.

The Ping Ting Chau district is one of the largest anthracite coal beds of which there is any knowledge. The natives get at the coal by adit or by shaft, as may best suit the nature of the ground. Shafts vary from 6 to 8 feet in diameter, and from 60 to 300 feet in depth; the thickness of the seam of coal varies from 4 to 18 feet. During late years native mechanics have been giving advice, with the result that collieries are coming into existence in which the coal is hoisted in baskets, and cow-hide bags are used for hauling out accumulations of water. A Canton Chinaman attempted to apply up-to-date methods to a mine just outside the Ping Ting Chau area, and sank a shaft beside the adit. He proposed to use a winch for winding up the coal, but before this could be done water was struck and the mine flooded. Boilers and pumps were erected by Chinese workmen, and the water was successfully cleared out of the first level. Shortly after starting work an explosion took place, and practically closed the shaft. At present the men are carrying the coal up the steps in bags in an excessively high temperature due to the steam-pipes, and the Cantonese has retired from the field. Pick, hammer, and wedge are the only tools used.

THE DYNAMICS OF A GOLF BALL.[1]

THERE are so many dynamical problems connected with golf that a discussion of the whole of them would occupy far more time than is at my disposal this evening. I shall not attempt to deal with the many important questions which arise when we consider the impact of the club with the ball, but confine myself to the consideration of the flight of the ball after it has left the club. This problem is in any case a very interesting one; it would be even more interesting if we could accept the explanations of the behaviour of the ball given by many contributors to the very voluminous literature which has collected round the game; if these were correct, I should have to bring before you this evening a new dynamics, and announce that matter, when made up into golf balls, obeys laws of an entirely different character from those governing its action when in any other condition.

If we could send off the ball from the club, as we might from a catapult, without spin, its behaviour would be regular, but uninteresting; in the absence of wind its path would keep in a vertical plane; it would not deviate

FIG. 1.

either to the right or to the left, and would fall to the ground after a comparatively short carry.

But a golf ball when it leaves the club is only in rare cases devoid of spin, and it is spin which gives the interest, variety, and vivacity to the flight of the ball. It is spin which accounts for the behaviour of a sliced or pulled ball, it is spin which makes the ball soar or "douk," or execute those wild flourishes which give the impression that the ball is endowed with an artistic temperament, and performs these eccentricities as an acrobat might throw in an extra somersault or two for the fun of the thing. This view, however, gives an entirely wrong impression of the temperament of a golf ball, which is, in reality, the most prosaic of things, knowing while in the air only one rule of conduct, which it obeys with unintelligent conscientiousness, that of always following its nose. This rule is the key to the behaviour of all balls when in the air, whether they are golf balls, base balls, cricket balls, or tennis balls. Let us, before entering into the reason for this rule, trace out some of its consequences. By the nose of the ball we mean the point on the ball furthest in front. Thus if, as in Fig. 1, C the centre of the ball is moving horizontally to the right, A will be the nose of the ball; if it is moving horizontally to the left, B will

[1] Discourse delivered at the Royal Institution on Friday, March 18, by Sir J. J. Thomson, F.R.S.

be the nose. If it is moving in an inclined direction CP, as in Fig. 2, then A will be the nose.

Now let the ball have a spin on it about a horizontal axis, and suppose the ball is travelling horizontally as in Fig. 3, and that the direction of the spin is as in the

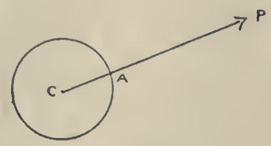

FIG. 2.

figure, then the nose A of the ball is moving upwards, and since by our rule the ball tries to follow its nose, the ball will rise and the path of the ball will be curved as in the dotted line. If the spin on the ball, still about a horizontal axis, were in the opposite direction, as in

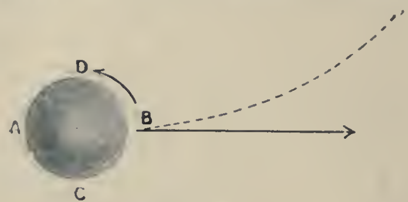

FIG. 3.

Fig. 4, then the nose A of the ball would be moving downwards, and as the ball tries to follow its nose it will duck downwards, and its path will be like the dotted line in Fig. 4.

Let us now suppose that the ball is spinning about a

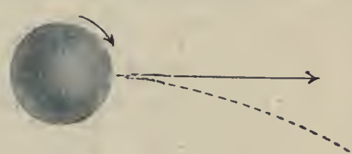

FIG. 4.

vertical axis, then if the spin is as in Fig. 5, as we look along the direction of the flight of the ball the nose is moving to the right; hence by our rule the ball will move off to the right, and its path will resemble the dotted line in Fig. 5; in fact, the ball will behave like a sliced ball.

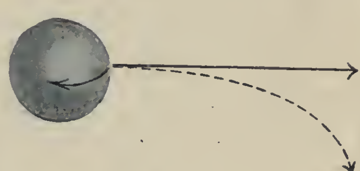

FIG. 5.

Such a ball, as a matter of fact, has spin of this kind about a vertical axis.

If the ball spins about a vertical axis in the opposite direction, as in Fig. 6, then, looking along the line of flight, the nose is moving to the left, hence the ball moves

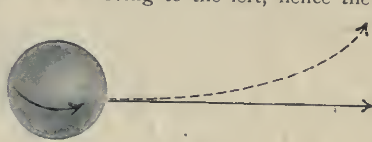

FIG. 6.

off to the left, describing the path indicated by the dotted line; this is the spin possessed by a "pulled" ball.

If the ball were spinning about an axis along the line of flight, the axis of spin would pass through the nose of the ball, and the spin would not affect the motion of the nose; the ball, following its nose, would thus move on without deviation.

Thus, if a cricket ball were spinning about an axis parallel to the line joining the wickets, it would not swerve in the air; it would, however, break in one way or the other after striking the ground; if, on the other hand, the ball were spinning about a vertical axis, it would swerve while in the air, but would not break on hitting the ground. If the ball were spinning about an axis intermediate between these directions it would both swerve and break.

Excellent examples of the effect of spin on the flight of a ball in the air are afforded in the game of base ball; an expert pitcher, by putting on the appropriate spins, can make the ball curve either to the right or to the left, upwards or downwards; for the sideway curves the spin must be about a vertical axis, for the upward or downward ones about a horizontal axis.

A lawn-tennis player avails himself of the effect of spin when he puts "top spin" on his drives, *i.e.* hits the ball on the top so as to make it spin about a horizontal axis, the nose of the ball travelling downwards, as in Fig. 4; this makes the ball fall more quickly than it otherwise would, and thus tends to prevent it going out of the court.

Before proceeding to the explanation of this effect of spin, I will show some experiments which illustrate the point we are considering. As the forces acting on the ball depend on the *relative* motion of the ball and the air, they will not be altered by superposing the same velocity on the air and the ball; thus, suppose the ball is rushing forward through the air with the velocity V, the forces will be the same if we superpose on both air and ball a velocity equal and opposite to that of the ball; the effect of this is to reduce the centre of the ball to rest, but to

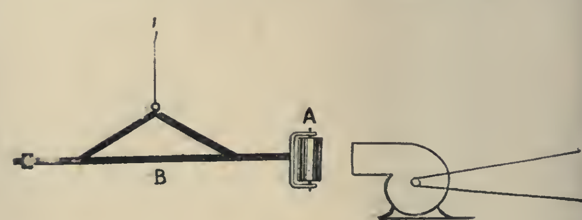

FIG. 7.

make the air rush past the ball as a wind moving with the velocity V. Thus the forces are the same when the ball is moving and the air at rest, or when the ball is at rest and the air moving. In lecture experiments it is not convenient to have the ball flying about the room; it is much more convenient to keep the ball still and make the air move.

The first experiment I shall try is one made by Magnus in 1852; its object is to show that a rotating body moving relatively to the air is acted on by a force in the direction in which the nose of the body is moving relatively to its centre; the direction of this force is thus at right angles both to the direction in which the centre of the body is moving and also to the axis about which the body is spinning. For this purpose a cylinder A (Fig. 7) is mounted on bearings so that it can be spun rapidly about a vertical axis; the cylinder is attached to one end of the beam B, which is weighted at the other end, so that when the beam is suspended by a wire it takes up a horizontal position. The beam yields readily to any horizontal force, so that if the cylinder is acted on by such a force this will be indicated by the motion of the beam. In front of the cylinder there is a pipe. D, through which a rotating fan driven by an electric motor sends a blast of air which can be directed against the cylinder. I adjust the beam and the beam carrying the cylinder so that the blast of air strikes the cylinder symmetrically; in this case, when the cylinder is not rotating the impact against it of the stream of air does not give rise to any motion of the beam. I now spin the cylinder, and you see that when the blast strikes against it the beam moves off sideways. It goes off one way when the spin is in one direction, and in the opposite way when the direction of spin is reversed.

The beam, as you will see, rotates in the same direction as the cylinder, which an inspection of Fig 8 will show you is just what it would do if the cylinder were acted upon by a force in the direction in which its nose (which, in this case, is the point on the cylinder first struck by the blast) is moving. If I stop the blast the beam does not move, even though I spin the cylinder, nor does it move when the blast is in action if the rotation of the cylinder is stopped; thus both spin of the cylinder and

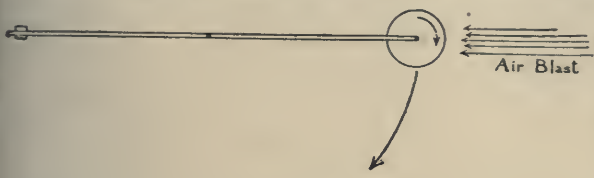

FIG. 8.

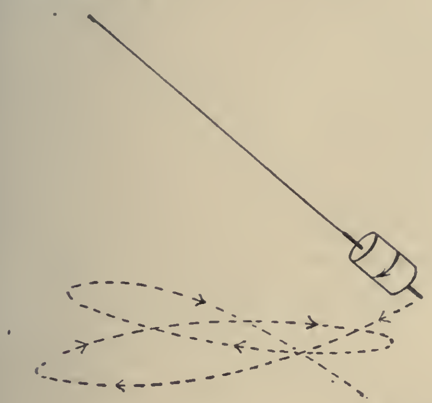
movement of it through the air are required to develop the force on the cylinder.

Another way of showing the existence of this force is to take a pendulum the bob of which is a cylinder, or some other symmetrical body, mounted so that it can be set in rapid rotation about a vertical axis. When the bob of the pendulum is not spinning the pendulum keeps swinging in one plane, but when the bob is set spinning the plane in which the pendulum swings no longer remains stationary, but rotates slowly in the same sense as the bob is spinning (Fig. 9).

and the other having the ordinary bramble markings, are mounted on an axis, and can be set in rapid rotation by an electric motor. An air-blast produced by a fan comes through the pipe B, and can be directed against the balls; the instrument is provided with an arrangement by which the supports of the axis carrying the balls can be raised or lowered so as to bring either the smooth or the bramble-marked ball opposite to the blast. The pressure is measured in the following way:—LM are two tubes connected with the pressure-gauge PQ; L and M are placed so that the golf balls can just fit in between them; if the pressure of the air on the side M of the balls is greater than that of the side L, the liquid on the right-hand side Q of the pressure-gauge will be depressed; if, on the other hand, the pressure at L is greater than that at M, the left-hand side P of the gauge will be depressed.

I first show that when the golf balls are not rotating there is no difference in the pressure on the two sides when the blast is directed against the balls; you see there is no motion of the liquid in the gauge. Next I stop the blast and make the golf balls rotate; again there is no motion in the gauge. Now when the golf balls are spinning in the direction indicated in Fig. 11 I turn on the blast, the liquid falls on the side Q of the gauge, rises on the other side. Now I reverse the direction of rotation of the balls, and you see the motion of the liquid in the gauge is reversed, indicating that the high pressure has gone from one side to the other. You see that the pressure is higher on the side M, where the spin carries this side of the ball into the blast, than on L, where the spin tends to carry the ball away from the blast. If we could



F G. 9.

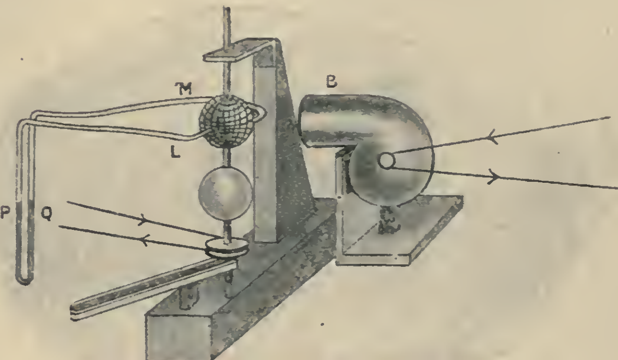


FIG. 11.

We shall now pass on to the consideration of how these forces arise. They arise because when a rotating body is moving through the air the pressure of the air on one side of the body is not the same as that on the other; the pressures on the two sides do not balance, and thus the body is pushed away from the side where the pressure is greatest.

Thus, when a golf ball is moving through the air, spinning in the direction shown in Fig. 10, the pressure

FIG. 10.

on the side ABC, where the velocity due to the spin conspires with that of translation, is greater than that on the side ADB, where the velocity due to the spin is in the opposite direction to that due to the translatory motion of the ball through the air.

I will now try to show you an experiment which proves that this is the case, and also that the difference between the pressure on the two sides of the golf ball depends upon the roughness of the ball.

In this instrument, Fig. 11, two golf balls, one smooth

imagine ourselves on the golf ball, the wind would be stronger on the side M than on L, and it is on the side of the strong wind that the pressure is greatest. The case when the ball is still and the air moving from right to left is the same from the dynamical point of view as when the air is still and the ball moves from left to right; hence we see that the pressure is greatest on the side where the spin makes the velocity through the air greater than it would be without spin.

Thus, if the golf ball is moving as in Fig. 12, the spin increases the pressure on the right of the ball and diminishes the pressure on the left.

To show the difference between the smooth ball and the rough one, I bring the smooth ball opposite the blast; you observe the difference between the levels of the liquid in the two arms of the gauge. I now move the rough ball into the place previously occupied by the smooth one, and you see that the difference of the levels is more than doubled, showing that with the same spin and speed of air blast the difference of pressure for the rough ball is more than twice that for the smooth.

We must now go on to consider why the pressure of the air on the two sides of the rotating ball should be different. The gist of the explanation was given by Newton nearly 250 years ago. Writing to Oldenburg in 1671 about the dispersion of light, he says, in the course of his letter:—"I remembered that I had often seen a tennis ball struck with an oblique racket describe such a curved line. For

a circular as well as progressive motion being communicated to it by that stroke, its parts on that side where the motions conspire must press and beat the contiguous air more violently, and there excite a reluctancy and reaction of the air proportionately greater." This letter has more than a scientific interest—it shows that Newton set an excellent precedent to succeeding mathematicians and physicists by taking an interest in games. The same explanation was given by Magnus, and the mathematical theory of the effect is given by Lord Rayleigh in his paper on "The Irregular Flight of a Tennis Ball," published in the *Messenger of Mathematics*, vol. vi., p. 14, 1877. Lord Rayleigh shows that the force on the ball resulting from this pressure difference is at right angles to the direction of motion of the ball, and also to the axis of spin, and that the magnitude of the force is proportional to the velocity of the ball multiplied by the velocity of spin, multiplied by the sine of the angle between the direction of motion of the ball and the axis of spin. The analytical investigation of the effects which a force of this type would produce on the movement of a golf ball has been discussed very fully by Prof. Tait, who also made a very interesting series of experiments on the velocities and spin of golf balls when driven from the tee, and the resistance they experience when moving through the air.

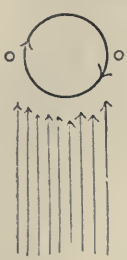

FIG. 12.

As I am afraid I cannot assume that all my hearers are expert mathematicians, I must endeavour to give a general explanation, without using symbols, of how this difference of pressure is established.

Let us consider a golf ball (Fig. 13) rotating in a current of air flowing past it. The air on the lower side of the ball will have its motion checked by the rotation of the ball, and will thus in the neighbourhood of the ball move more slowly than it would do if there were no golf ball present, or than it would do if the golf ball were there but was not spinning. Thus if we consider a stream of air flowing along the channel PQ, its velocity when near the ball at Q must be less than its velocity when it started at P; there must, then, have been pressure acting against the motion of the air as it moved from P to Q, *i.e.* the pressure of the air at Q must be greater than at a place like P, which is some distance from the ball. Now let us consider the other side of the ball; here the spin tends to carry the ball in the direction of the blast of air; if the velocity of the surface of the ball is greater than that of the blast, the ball will increase the velocity of the blast on this side, and if the velocity of the ball is less than that of the blast, though it will diminish the velocity of the air, it will not do so to so great an extent as on the other side of the ball. Thus the increase in pressure of the air at the top of the ball over that at P, if it exists at all, will be less than the increase in pressure at the bottom of the ball. Thus the pressure at the bottom of the ball will be greater than that at the top, so that the ball will be acted on by a force tending to make it move upwards.

side of the boat they have to face the wind, on the other side they have the wind at their backs. Now when they face the wind, the pressure of the wind against them is greater than if they were at rest, and this increased pressure is exerted in all directions, and so acts against the part of the ship adjacent to the deck; when they are moving with their backs to the wind the pressure against their backs is not so great as when they were still, so the pressure acting against this side of the ship will not be so great. Thus the rotation of the passengers will increase the pressure on the side of the ship when they are facing the wind and diminish it on the other side. This case is quite analogous to that of the golf ball.

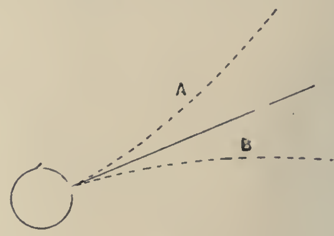

FIG. 14.

The difference between the pressures on the two sides of the golf ball is proportional to the velocity of the ball multiplied by the velocity of the spin. As the spin imparted to the ball by a club with a given loft is proportional to the velocity with which the ball leaves the club, the difference of pressure when the ball starts is proportional to the square of its initial velocity. The difference between the average pressures on the two sides of the ball need only be about one-fifth of 1 per cent. of the atmospheric pressure to produce a force on the ball greater than its weight. The ball leaves the club in a good drive with a velocity sufficient to produce far greater pressures than this. The consequence is that when the ball starts from the tee spinning in the direction shown in Fig. 14, this is often called underspin; the upward force due to the spin is greater than its weight, thus the resultant force is upwards, and the ball is repelled from the earth instead of being attracted to it. The consequence is that the path of the ball curves upward as in the curve A instead of downwards as in B, which would be its path if it had no spin. The spinning golf ball is, in fact, a very efficient heavier-than-air flying machine; the lifting force may be many times the weight of the ball.

The path of the golf ball takes very many interesting forms as the amount of spin changes. We can trace all these changes in the arrangement which I have here, and which I might call an electric golf links. With this apparatus I can subject small particles to forces of exactly the same type as those which act on a spinning golf ball.

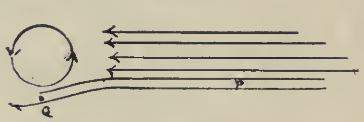

FIG. 13.

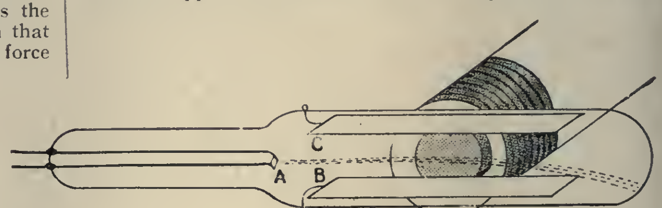

FIG. 15.

We have supposed here that the golf ball is at rest, and the air rushing past it from right to left; the forces are just the same as if the air were at rest, and the golf ball rushing through it from left to right. As in Fig. 13, such a ball rotating in the direction shown in the figure will move upwards, *i.e.* it will follow its nose.

It may perhaps make the explanation of this difference of pressure easier if we take a somewhat commonplace example of a similar effect. Instead of a golf ball, let us consider the case of an Atlantic liner, and, to imitate the rotation of the ball, let us suppose that the passengers are taking their morning walk on the promenade deck, all circulating round the same way. When they are on one

These particles start from what may be called the tee A (Fig. 15). This is a red-hot piece of platinum with a spot of barium oxide upon it; the platinum is connected with an electric battery which causes negatively electrified particles to fly off the barium and travel down the glass tube in which the platinum strip is contained; nearly all the air has been exhausted from this tube. These particles are luminous, so that the path they take is very easily observed. We have now got our golf balls off from the tee; we must now introduce a vertical force to act upon them to correspond to the force of gravity on the golf ball. This is easily done by the horizontal plates BC, which are electrified by connecting them with an electric

battery; the upper one is electrified negatively, hence when one of these particles moves between the plates it is exposed to a constant downwards force, quite analogous to the weight of the ball. You see now when the particles pass between the plates their path has the shape shown in Fig. 16; this is the path of a ball without spin. I can imitate the effect of spin by exposing the particles while they are moving to magnetic force, for the theory of these particles shows that when a magnetic force acts upon them it produces a mechanical force which is at right angles

FIG. 16.

to the direction of motion of the particles, at right angles also to the magnetic force, and proportional to the product of the velocity of the particles, the magnetic force, and the sine of the angle between them. We have seen that the force acting on the golf ball is at right angles to the direction in which it is moving at right angles to the axis of spin, and proportional to the product of the velocity of the ball, the velocity of spin, and the sine of

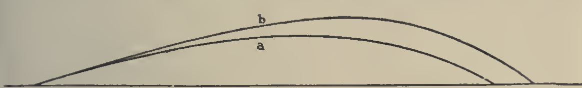

FIG. 17.

the angle between the velocity and the axis of spin. Comparing these statements, you will see that the force on the particle is of the same type as that on the golf ball if the direction of the magnetic force is along the axis of spin and the magnitude of the force proportional to the velocity of spin, and thus if we watch the behaviour of these particles when under the magnetic force we shall get an indication of the behaviour of the spinning golf

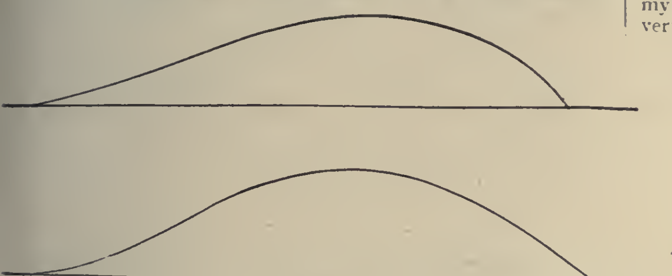

FIG. 18.

ball. Let us first consider the effect of underspin on the flight of the ball; in this case the ball is spinning, as in Fig. 3, about a horizontal axis at right angles to the direction of flight. To imitate this spin I must apply a horizontal magnetic force at right angles to the direction

FIG. 19.

of flight of the particles. I can do this by means of the electromagnet. I will begin with a weak magnetic force, representing a small spin. You see how the path differs from the one when there was no magnetic force; the path, to begin with, is flatter, though still concave, and the carry is greater than before—see Fig. 17, *a*. I now increase the strength of the magnetic field, and you will see that the carry is still further increased, Fig. 17, *b*. I increase the spin still further, and the initial path becomes convex instead of concave, with a still further increase in carry, Fig. 18. Increasing the force still more, you see the particle soars to a great height, then comes suddenly down, the carry now being less than in the previous case (Fig. 19). This is still a familiar type of the path of the golf ball. I now increase the magnetic force still further, and now we get a type of flight not to my knowledge ever observed in a golf ball, but which would be produced if we could put on more spin than

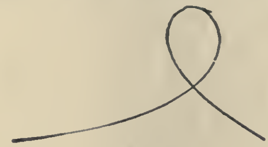

FIG. 20.

we are able to do at present. You see there is a kink in the curve, and at one part of the path the particle is actually travelling backwards (Fig. 20). Increasing the magnetic force I get more kinks, and we have a type of drive which we have to leave to future generations of golfers to realise (Fig 21).

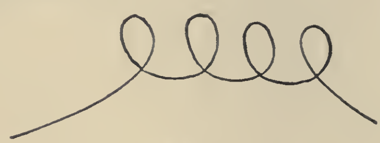

FIG. 21.

By increasing the strength of the magnetic field I can make the curvature so great that the particles fly back behind the tee, as in Fig. 22.

So far I have been considering underspin. Let us now illustrate slicing and pulling; in these cases the ball is spinning about a vertical axis. I must therefore move my electromagnet, and place it so that it produces a vertical magnetic force (Fig. 23). I make the force act

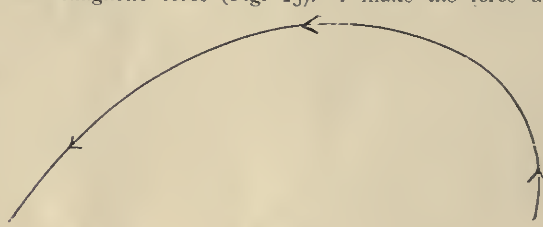

FIG. 22.

one way, say downwards, and you see the particles curve away to the right, behaving like a sliced ball. I reverse the direction of the force and make it act upwards, and the particles curve away to the left, just like a pulled ball.

By increasing the magnetic force we can get slices and

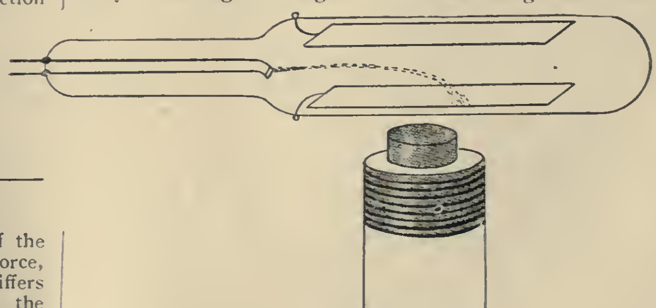

FIG. 23.

pulls much more exuberant than even the worst we perpetrate on the links.

Though the kinks shown in Fig. 20 have never, so far as I am aware, been observed on a golf links, it is quite easy to produce them if we use very light balls. I have

here a ball A made of very thin indiarubber of the kind used for toy balloons, filled with air, and weighing very little more than the air it displaces; on striking this with the hand, so as to put underspin upon it, you see that it describes a loop, as in Fig. 24.

Striking the ball so as to make it spin about a vertical axis, you see that it moves off with a most exaggerated slice when its nose is moving to the right looking at it from the tee, and with an equally pronounced pull when its nose is moving to the left.

One very familiar property of slicing and pulling is that the curvature due to them becomes much more pronounced when the velocity of the ball has been reduced than it was at the beginning when the velocity was greatest. We can easily understand why this should be so if we consider the effect on the sideways motion of reducing the velocity to one half. Suppose a ball is pro-

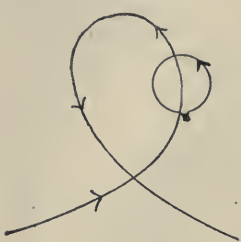

FIG. 24.

FIG. 25.

jected from A in the direction AB, but is sliced; let us find the sideways motion BC due to slice. The sideways force is, as we have seen, proportional to the product of the velocity of the ball and the velocity of spin, or, if we keep the spin the same in the two cases, to the velocity of the ball; hence, if we halve the velocity we halve the sideways force, hence, in the same time, the displacement would be halved too, but when the velocity is halved the time taken for the ball to pass from A to B is doubled. Now the displacement produced by a constant force is proportional to the square of the time; hence, if the force had remained constant, the sideways deflection BC would have been increased four times by halving the velocity, but as halving the velocity halves the force, BC is doubled when the velocity is halved; thus the sideways movement is twice as great when the velocity is halved.

If the velocity of the spin diminished as rapidly as that of translation, the curvature would not increase as the velocity diminished, but the resistance of the air has more effect on the speed of the ball than on its spin, so that the speed falls the more rapidly of the two.

The general effect of wind upon the motion of a spinning ball can easily be deduced from the principles we discussed in the earlier part of the lecture. Take, first, the case of a head-wind. This wind increases the relative velocity of the ball with respect to the air; since the force due to the spin is proportional to this velocity, the wind

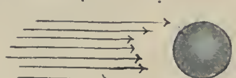

FIG. 26.

increases this force, so that the effects due to spin are more pronounced when there is a head-wind than on a calm day. All golfers must have had only too many opportunities of noticing this. Another illustration is found in cricket; many bowlers are able to swerve when bowling against the wind who cannot do so to any considerable extent on a calm day.

Let us now consider the effect of a cross-wind. Suppose the wind is blowing from left to right, then, if the ball is pulled, it will be rotating in the direction shown in Fig. 26; the rules we found for the effect of rotation on the difference of pressure on the two sides of a ball in a blast of air show that in this case the pressure on the front half of the ball will be greater than that on the rear half, and thus tend to stop the flight of the ball. If, however, the spin was that for a slice, the pressure on the rear half would be greater than the pressure in front, so that the difference in pressure would tend to push on the ball and make it travel further than it otherwise would. The moral of this is that if the wind is coming from the left we should play up into the wind and slice the ball, while if it is coming from the right we should play up into it and pull the ball.

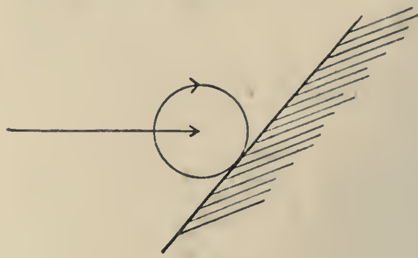

FIG. 27.

I have not time for more than a few words as to how the ball acquires the spin from the club. But if you grasp the principle that the action between the club and the ball depends only on their *relative* motion, and that it is the same whether we have the ball fixed and move the club or have the club fixed and project the ball against it, the main features are very easily understood.

Suppose Fig. 27 represents the section of the head of a

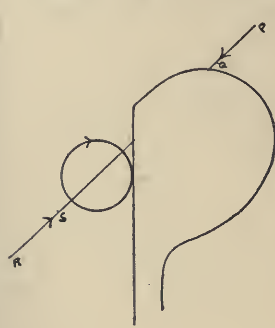

FIG. 28.

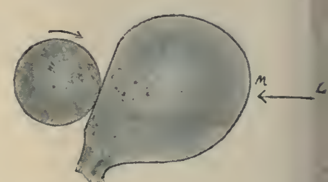

FIG. 29.

lofted club moving horizontally forward from right to left, the effect of the impact will be the same as if the club were at rest and the ball were shot against it horizontally from left to right. Evidently, however, in this case the ball would tend to roll up the face, and would thus get spin about a horizontal axis in the direction shown in the figure; this is underspin, and produces the upward force which tends to increase the carry of the ball.

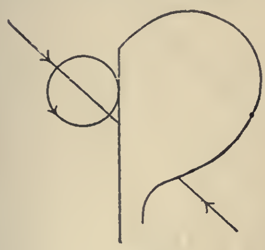

FIG. 30.

FIG. 31.

Suppose, now, the face of the club is not square to its direction of motion, but that, looking down on the club, its line of motion when it strikes the ball is along PQ (Fig. 28), such a motion as would be produced if the arms were pulled in at the end of the stroke, the effect of the impact now will be the same as if the club were at rest and the ball projected along RS, the ball will endeavour to roll along the face away from the striker; it will spin

in the direction shown in the figure about a vertical axis. This, as we have seen, is the spin which produces a slice. The same spin would be produced if the motion of the club was along LM and the face turned so as to be in the position shown in Fig. 29, *i.e.* with the heel in front of the toe.

If the motion and position of the club were as in Figs. 30 and 31, instead of as in Figs. 28 and 29, the same consideration would show that the spin would be that possessed by a pulled ball.

THE SECOND FRENCH ANTARCTIC EXPEDITION.[1]

THE Antarctic is so vast as to admit of many expeditions working together with good results, and Dr. Charcot therefore resolved to return to the region which he had explored to some extent in 1903–5. His precise object was to investigate from every point of view as great an extent of the Antarctic as possible, without any considerations as to latitude. He desired to enter the region where the ice drifted furthest to the north, and he had no hope whatever of reaching the Pole. He had a three-masted vessel constructed at St. Malo, with auxiliary engine, which he named *Le Pourquoi Pas?* It was equipped with every care, and supplied with the most modern instruments for observation. The crew consisted of twenty-two men, most of whom had already accompanied Dr. Charcot on his previous expedition. The staff consisted of seven, who were experts in different departments of science. The expedition started from Havre on August 15, 1909, and on December 16 left Punta Arenas for the Antarctic.

After passing Deception Island Dr. Charcot made for Port Lockroy, in Gerlache Strait, where the work of the expedition began. Some days later the expedition arrived at Wandell, which was found to be a very unsatisfactory harbour, and therefore the expedition moved on to Petermann Island. Dr. Charcot with two of his companions set out to discover if it was possible to pass between the Biscoe Islands and the coast. As they expected to return the same day they did not take any provisions or change of garments. Their return was blocked by the ice, and it was four days before they were able to reach the ship, narrowly escaping death from hunger and cold. From Petermann Island a journey was made towards the south along the coast, the mapping of which, begun during the previous expedition, was completed. A hydrographical survey was made of Adelaide Island, which was found to be seventy miles long instead of eight, as had previously been stated. To the south of Adelaide, in a region which had not previously been visited, a great gulf was discovered which was entitled Marguerite Bay. Here the greatest difficulties were met with from the ice and from icebergs, but these were successfully overcome. In spite of all the difficulties the expedition discovered and studied the hydrography of 120 miles of unknown coast to the south.

At last, after two attempts, the expedition succeeded in traversing the ice and reaching Alexander Land, which was mapped, and the hydrography of which was investigated. It was found absolutely impossible to winter here, however, and the expedition was compelled to return to Petermann Island. Observations, however, were carried on with great perseverance, numerous soundings and dredgings were made, and many photographs taken. The house which had been constructed here on the previous expedition was still available, and after three days' work was put into condition for being able to be used during the winter. In the autumn numerous and long excursions were made on the glaciers. The winter, though mild, was almost continuously stormy, a formidable north-east wind blowing during nine months. An immense quantity of snow fell. The terrible season was very trying to the members of the expedition, some of whom had been attacked with scurvy.

An attempt was made to traverse Graham Land. The members of the expedition who carried out the work returned with many interesting observations, but without having been able to overcome the impassable perpendicular wall of granite and of ice which lines the whole of the coast where a landing was attempted to be made. Many other excursions were made in the neighbourhood. With great difficulty, owing to the state of the ice, Deception Island was reached at the end of November, and the expedition received the greatest hospitality from the whalers who are settled on the island. Many observations were here made in seismography, on the tides, on hydrography, in natural history and geology, and many soundings and dredgings were carried out.

After the expedition had been refitted it visited Bridgman Island, Admiralty Bay, the south coast of the South Shetlands, at all of which places good work was done. After this another attempt was made to penetrate southwards. In spite of the unfavourable condition of the ice and the weather, the expedition succeeded in passing beyond all the latitudes previously reached to the southwest of Alexander Land. It was hoped that the expedition would be able to make further discoveries to the south and the west of Alexander Land, but the formidable condition of the pack rendered this extremely difficult. The route, however, was continued along the edge of the pack, when Peter 1st Island was discovered in the place at which it is usually charted. After this the icebergs became so numerous as to be embarrassing and dangerous. Dr. Charcot reckons that they counted something like 5000 of these in one day. However, they succeeded in reaching 126 degrees west longitude, and so reached two or three degrees further south than the route followed by Cook and Bellingshausen. As the supply of coal was now almost exhausted, and the health of the expedition had become alarming, it was decided to make for the north. The icebergs gradually diminished, and at last disappeared, and, thanks to an uninterrupted series of strong winds, varying from south-west to N.N.W., rapid progress was made. In ten days the Straits of Magellan were reached, and on February 12 the expedition anchored at Punta Arenas. The *Pourquoi Pas?* behaved admirably in spite of the many trials to which it was subjected, and the crew was all that could be desired, while the scientific staff worked incessantly, and from the scientific point of view the programme was scrupulously carried out. It will take many months to work out the observations which have been made during the expedition, to study and arrange the rich collections obtained, and therefore it is somewhat difficult to give more than a brief *résumé* of the results obtained.

From the geographical point of view the expedition has proved that the west coast of what may be called the South American Antarctic is cut up by deep fjords, and the coast studded with islands and reefs. Graham Land is continued to the south by a land to which Dr. Charcot has given the name Terre Loubet; this is continued by the Terre Fallières. Alexander Land, which has only been seen by Bellingshausen, is a large island, but the lands discovered by the expedition to the south and west of that very probably join on Terre Fallières. Outside of Peter 1st Island the expedition did not obtain sight of any other land, but their soundings in continuation of those of the Belgian expedition, the configuration of the icebergs and their movements, seem to indicate that there exists a continual line, which most probably joints the Graham Land section of the Antarctic to King Edward VII. Land. Dr. Charcot considers that the further exploration of this land is very desirable, although the difficulties from the state of the weather and the formidable nature of the ice here will render such an enterprise extremely difficult.

In spite of the difficulties which had to be faced, the observations made in the various departments of science are extremely rich. Careful mapping of the lands visited was carried out throughout; numerous gravity observations were made; earthquake phenomena recorded; an eclipse of the sun on December 23, 1908, was observed; important geological observations carried out, proving that the same dioritic and granitic forms which are to be found in Graham Land are continued further to the south. Of the existence of a continental plateau there can be little doubt from the observations that were made. Numerous excursions were made on the glaciers into the interior: careful continuous meteorological observations were re-

[1] Summary of a paper by Dr. J. B. Charcot read before the Royal Geographical Society on December 19.

corded; 100 soundings were made; 200 specimens of the water collected; twenty dredgings were carried out; observations of interest in magnetism, in solar radiation, zoological and botanical collections, and additions to our knowledge in other directions, rendering the expedition from the scientific point of view completely successful.

COMPARISONS OF JURASSIC FLORAS.

At the forty-ninth annual meeting of the Yorkshire Naturalists' Union, held at Middlesbrough on Saturday, December 17, Prof. A. C. Seward, F.R.S., delivered his presidential address, entitled "The Jurassic Flora of the East of Yorkshire in Relation to the Jurassic Floras of the World." It was pointed out that the estuarine beds of east Yorkshire were among the most famous and important strata of the world from the point of view of their fossil contents. Since the publication in 1822 of Young and Bird's "Geological Survey of the Yorkshire Coast" much attention has been paid to the fossil plants of Yorkshire by British and foreign students. During the first half of the nineteenth century a considerable amount of work was done by such pioneers as William Bean, John Williamson, W. Crawford Williamson, John Phillips, and others. Prof. Seward gave a general sketch of the flora which the labours of Yorkshire naturalists have enabled students to investigate. Prof. Nathorst, of Stockholm, who has more than once invaded our shores, recently transported a portion of our island to his country. By establishing a department devoted to the floras of the past, the Swedish Academy has set an example which the trustees of our national collections would do well to imitate. Palæobotany is still without a representative in the British Museum!

Prof. Seward then reviewed the various fossil remains of Algæ and Fungi, Hepophyta, Equisetales, Lycopodiales, Filicales, Gymnospermæ, Ginkgoales, and Coniferales, being some of the types which occur in the Yorkshire strata. The Yorkshire coast flora is characterised by the abundance of ferns and cycads and certain types of conifers, though as yet it is not possible to make any statement as to the relative abundance of these different groups. It is also probable that the Ginkgoales played a fairly prominent part in the composition of the vegetation. The most interesting fact in regard to the Jurassic ferns is that they afford strong presumptive evidence in support of the view that their nearest living allies are to be sought in the southern hemisphere. As regards the cycads, comparison with recent genera is rendered more difficult because of the greater gulf between recent members of the group and those which flourished in the Jurassic era. There can, however, be no reasonable doubt that the cycads of to-day are derived from an ancient stock which produced also Williamsonia and other Jurassic genera. Here, again, the recent plants most nearly akin to those of the Mesozoic floras are chiefly characteristic of southern and warmer regions. The same general statement is applicable to the relation of some of the Jurassic conifers to recent types. Finally, in the genus Ginkgo of the Jurassic flora we have a member of a group which would probably have ceased to be represented among living plants were it not for the fact that the recent species has been long held in veneration in the Far East as a sacred tree. With these southern forms there grew in profusion stalwart Equisetums, which afforded one of the few instances of a genus still represented by several species in the British flora which can claim a Jurassic ancestry.

At first sight one might be tempted to infer that there is clear evidence of a tropical, or at least subtropical, climate in Jurassic Europe. This would, perhaps, be a correct conclusion, but it is one which cannot be confidently made, so far, at least, as the botanical evidence is concerned. The fact must be borne in mind that among living plants very closely allied types, or even one of the same species, may flourish under widely different climatic conditions, as in the case of our own familiar bracken fern, which appears to be equally at home on the Yorkshire moors, in Tasmania, Abyssinia, and elsewhere. The comparison of a past with a recent flora is bound up with numerous considerations in addition to those connected with the comparison of existing and extinct species. During the Rhætic and Jurassic eras, and in the succeeding Cretaceous and Tertiary epochs, the genus Ginkgo was very widely distributed in Europe. So recently as the Lower Tertiary period it existed in what is now the west of Scotland in a form hardly distinguishable from the maiden-hair tree. Are we justified in assuming that the living species is a safe criterion as regards power of resistance or capabilities of life with which the family was endowed at the zenith of its vigour? Were it possible to learn from the maiden-hair tree what vicissitudes its ancestors passed through since the days of the Jurassic period, we might hear of unequal competition and gradual migration from northern to southern latitudes.

In dealing with the relation of the Yorkshire Jurassic flora with that of other parts of the world, it is remarkable to find that almost precisely similar plants to those occurring in the local rocks also are found embedded in strata of about the same age at places so far distant as Bornholm, Poland, Turkestan, Siberia, Korea, Japan, Franz Josef Land, Spitsbergen, Greenland, America, India, and Australia. This extraordinary distribution would certainly seem to indicate that the climate in Jurassic times must have been much more uniform the world over than obtains to-day.

As a result of Prof. Seward's address and his interest in the union's work, a committee was formed for the investigation of the Jurassic plants of Yorkshire, with Prof. Seward as first chairman.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Sheffield.—Mr. R. J. Pye-Smith has resigned the professorship of surgery. The council has adopted the following resolution:—"That the resignation of Mr. Pye-Smith as professor of surgery in the University be accepted with great regret. Mr. Pye-Smith, who is the senior member of the teaching staff, has been a teacher of surgery for thirty-four years, first in the old Medical School, next in the University College, and finally in the University, and the council desire to place on record their appreciation of the distinguished services which he has rendered to the cause of medical education in Sheffield."

Dr. E. W. Adams has been appointed to the post of lecturer in materia medica and assistant to the professor of materia medica, pharmacology, and therapeutics.

Dr. W. Goodwin, head of the chemical department at the South-Eastern Agricultural College, Wye, has been appointed principal of the Midland Agricultural College, Kingston, Derbyshire.

A Reuter message from Chicago announces that Mr. John D. Rockefeller has made a final donation of 2,000,000*l.* to Chicago University, making a total of approximately 7,000,000*l.* given by him to that institution.

The annual meeting of the Geographical Association will be held on Saturday, January 14, 1911, in the Lecture Hall, London School of Economics. The following short papers will be read:—Geography at seven years, Miss C. von Wyss; map-making as a school subject, F. Beames; practical contouring round a London school, J. Fairgrieve; the training of teachers in geography, J. F. Unstead. An address will be delivered by the president, Mr. Douglas W. Freshfield, and a lecture on "The Highways of England and Wales, Past and Present, and their Relationship to Geographical Conditions," by Mr. G. Montagu.

Liverpool.—The Liverpool School of Tropical Medicine (Incorporated) at the time of the death of the late Dr. J. E. Dutton in the Congo Free State, whilst investigating sleeping sickness and other tropical diseases there, started a fund to establish a chair in the University in his memory. The necessary amount has now been raised, mainly through the generosity of the late Sir Alfred Jones, Mr. W. H. Lever, Sir William Hartley, and many others. The Liverpool School has at present a lectureship in tropical entomology, and the committee decided, therefore, that the best form the memorial could take would be the foundation in the University of a Dutton professorship in tropical entomology. The value of close investigation into

the habits and life-cycles of disease-bearing biting insects, not only in the tropics, but also at home, is daily becoming more evident. Dr. Dutton was one who realised this intensely, and it is fitting that his memorial should take the form of a chair of medical entomology. The appointment to the chair has not yet been made by the University, but will be announced in due course.

An agreement has been arrived at between the Senate of the Queen's University of Belfast and the Corporation of Belfast by which the work of the University and of the Belfast Municipal Technical Institute will be coordinated. As the Vice-Chancellor of the University said at the meeting of the Senate on December 15, when the agreement was made, this will afford an opportunity to young men in Belfast of obtaining a complete education in such subjects as mechanical engineering, electrical engineering, chemical technology, textile technology, and naval architecture, and of securing the degree of B.Sc. at the conclusion of their course of work. The advantages of this arrangement to the Technical Institute, on one hand, and to the University on the other, will be very great. By the proposed arrangement means will be provided for obtaining trained captains of industry for the various great enterprises for which Belfast is famous. The coordination forges another link between the University and the city. The technical subjects mentioned will be studied at the institute, which becomes an integral part of the University in a manner analogous to several cases in England. We learn, too, that a public textile testing and conditioning house has been started in connection with the institute at Belfast. The functions of the testing house are to be similar to those of other public textile testing and conditioning houses, namely, the examination of textile materials with the view of ascertaining and certifying their true weight, length, condition, and strength, and, in addition, the carrying out of such other tests and investigations as may be required in order that spinners, manufacturers, merchants, and others desirous of having tests conducted and an official certificate issued may effect their object through the medium of an independent public authority.

As the result of representations made by the Old Students Association of the Royal College of Science, London, of which Sir Thomas H. Holland, K.C.I.E., F.R.S., is president, the governing body of the Imperial College of Science and Technology has granted the privilege of wearing academic costume to associates of the Royal College of Science, London, a like privilege being also granted to associates of the Royal School of Mines, of the City and Guilds of London Institute, and to diplomate students of the Imperial College. Patterns for academic costume have been approved by the governing body. In each case the gown is as for the University of London B.A., of black silk or stuff, but with the forearm seam open, and without button, cord, or pleats. The hoods are differentiated for the several colleges as regards the colour of the neckband, which for A.R.C.S.'s will be white, for A.R.S.M.'s gold, for A.C.G.I.'s red (as in the Arms of the City of London), and black for diplomate students of the Imperial College, the hood in each case being as the Oxford University M.A. hood in size and shape, of black silk or stuff, partly lined with white watered silk to a depth of 6 inches, with an edging, 1 inch in width, of royal purple velvet, ½ inch from the outer edge, and with a neckband 1¼ inches in width, lined with white watered silk and edged with white watered silk ¼ inch in width. As regards the Associates of the Royal College of Science, the decision of the governing body removes a grievance of long standing, which was felt more especially by teachers in secondary and technical schools. It is generally recognised that the A.R.C.S. diploma represents a course of training in no sense inferior to that represented by a university degree and there is therefore no reason why an invidious distinction should be made between university graduates and associates of the college in respect of academic costume. The claim of associates to the privilege is strengthened by the fact that it has been granted to associates of various London colleges, such as the Royal College of Art, King's College, the Royal College of Organists, and the College of Preceptors. Several London firms of robe-makers have undertaken to supply academic costume of the approved patterns.

Sir Alfred Keogh, Rector of the Imperial College of Science and Technology, delivered an address at the Woolwich Polytechnic on Saturday, December 17, on the occasion of the nineteenth annual prize distribution. In the course of his remarks he said:—There are certain subjects engaging our attention at the present moment which are of enormous importance to the future of the country. We have been told that we are losing our supremacy because we do not keep science and industry in close touch with one another; we are told that the manufacturers have not an appreciation of science, and as a consequence are being ousted in various directions by other people. However it may shock you to hear me say so, I have the greatest sympathy with the manufacturers. As a matter of fact, I know in this country there are manufacturers who have the greatest appreciation for scientific education, and are employing foreigners in their workshops because they have the required knowledge. The reason is this, that we are not providing the class of men this country needs, and until we do provide them the manufacturer will turn aside and get people from abroad. We have been told all this, we have been told that our industries are failing in consequence, and an effort was made—which has been passed unnoticed—to bring science and industries together and to coordinate general scientific education in London. Three of the great colleges at South Kensington—the City and Guilds College, the Royal College of Science, and the Royal School of Mines—were combined for the purpose of coordinating knowledge, and that incident passed almost unnoticed. The Imperial College was intended to coordinate the whole scientific education in London, and we have in London (I include, of course, Woolwich) a number of polytechnic institutions doing technical work, and we are not coordinated one with the other. If something could be done to coordinate the polytechnics with the Imperial College, I for one have no fear of the foreigner. This I earnestly hope will come about soon. Perhaps it may be possible to get the teachers in the polytechnics of London to recognise that there is one great need at the present moment, that professors and teachers should come together and devise a scheme to work for one solid purpose and one object, and that is the correlation of science and industrial work. I do not know what the opinion here is on this point, but we think at the Imperial College that there should be a great imperial college in London including this institution, including every other polytechnic, in which we shall be able to give our own degrees. The principals of the polytechnics have been called upon to express their opinion. I earnestly hope that they will not forget that upon their shoulders will rest the responsibility of saying whether these young men who are here to-night are simply to become B.Sc.'s and then to be thrown aside, or whether they are to become learned Britons to help forward the industries of our Empire; unless the polytechnics do come forward with their solution of the difficulty, then I can only tell you that some other authority will have to start other institutions.

SOCIETIES AND ACADEMIES.

London.

Royal Society, December 8.—Mr. A. B. Kempe, treasurer and vice-president, in the chair.—Sir W. de W. **Abney**: Colour-blindness and the trichromatic theory of colour-vision. Part ii.: Incomplete red or green blindness. In this paper the author continues the subject of the trichromatic theory of colour-vision and colour-blindness. In part i. he treated of complete colour-blindness, and in this paper, part ii., he treats of incomplete colour-blindness. He shows how the amount of incompleteness can be accurately determined from the luminosity curve of a colour-blind person both red and green blind. He also shows that the amount of incompleteness can be determined from observations made by the red- or green-blind at any part of the spectrum if someone with normal vision makes observations at the same place, using unchanged white light for the comparison. Incidentally, he shows

that the three sensation components of the different colours of the spectrum, as determined by himself, are verified by the results, and that the trichromatic theory fully accounts for all cases of incomplete colour-blindness which he has measured.—Lord **Rayleigh**: The sensibility of the eye to variations of wave-length in the yellow region of the spectrum.—Sir D. **Bruce** and others: Trypanosome diseases of domestic animals in Uganda. IV.: *Trypanosoma uniforme*, sp. nov.—Sir D. **Bruce** and others: Trypanosome diseases of domestic animals in Uganda. V.: *Trypanosoma nanum* (Laveran).—Major Ronald **Ross** and D. **Thomson**: Some enumerative studies on malarial fever. The object of these researches was to make a minute coordinated study of cases of malarial infection occurring in the Tropical Ward of the Royal Southern Hospital at Liverpool. The first care of the authors was to elaborate a method by which the number of parasites could be correctly counted, and the one which they adopted was to make a measured quantity of blood into a dehæmoglobinised thick-film, and then to count the organisms contained in it. Almost daily estimates of the number of parasites, with frequent estimates of the leucocytes, the hæmoglobin, and the excreted urobilin, were made since the beginning of this year in twenty-four cases of *Plasmodium falciparum*, eight cases of *P. vivax*, and one case of *P. malariae* and *P. falciparum*. Correlation with minor deviations was found between the number of asexual parasites present and the degree of fever. If the asexual forms did not number more than several hundreds per cm. they were not numerous enough in these cases to produce fever. The asexual forms do not disappear between relapses, as usually thought, but tend to diminish. It is roughly estimated from these cases that quinine reduces the asexual forms by 50 to 80 per cent.—G. C. E. **Simpson**: Hæmoglobin metabolism in malarial fever. (Preliminary note.) In the pyrexia of malaria there is a marked fall in the hæmoglobin of the blood, and further investigation of this question was undertaken in the hope that it might throw light on the relationship of malaria and blackwater fever. In benign tertian malaria a slightly increased output of urinary urobilin occurs, in malignant tertian malaria a greater increase, and in the malignant form mrked urobilinuria was sometimes found.—Major Ronald **Ross** and D. **Thomson**: A case of sleeping sickness studied by precise enumerative methods; further observations. *Conclusions*.—(1) The increase of trypanosomes is due to their active multiplication, depending on the following conditions:—(*a*) the liberation of a reproductive stimulant from the dead trypanosomes of the previous fall; (*b*) the small number of leucocytes, especially mononuclears; (*c*) the habituation of the trypanosomes to their antibodies; (*d*) the absence or diminution of antibodies. (2) The decrease of trypanosomes is due to their rapid death, and to a cessation of multiplication depending on the following conditions:—(*a*) the large increase of leucocytes, especially of mononuclears; (*b*) the formation of antibodies in the serum. (3) The trypanosomes remaining between the rises are resistent forms. (4) Extracts of dead cells would appear to stimulate the corresponding live cells to multiply or divide.—Dr. H. B. **Fantham** and J. G. **Thomson**: Enumerative studies on *Trypanosoma gambiense* and *Trypanosoma rhodesiense* in rats, guinea-pigs, and rabbits; periodic variations disclosed. (1) The strains of trypanosomes used in these investigations were:—(*a*) *T. gambiense*, old laboratory strain; (*b*) *T. rhodesiense* (Stephens and Fantham), from a patient suffering from sleeping sickness in Rhodesia. (2) Rats, guinea-pigs, and rabbits were inoculated with a definite number of trypanosomes, and daily counts were made of the parasites in the peripheral blood of the animals. (3) Periodic variation was found in all these animals comparable to that discovered by R. Ross and D. Thomson in the blood of the sleeping sickness patient. (4) Rats inoculated with each strain showed either a periodic increase or a continuous rise in the numbers of parasites. (5) The average life of rats inoculated with *T. rhodesiense* was 11·3 days, with *T. gambiense* 13·8 days. (6) The average incubation period in rats in the case of *T. rhodesiense* was 2·9 days, in *T. gambiense* 4·4 days. The average weights of the animals and the average number of parasites inoculated were approximately the same in the two strains. (7) In rats infected with *T. rhodesiense* the period between the crests of the graph was 3 to 4 days, while in *T. gambiense* this period was 4 to 6 days. (8) In guinea-pigs the trypanosomiasis tended to run a chronic course, but the life of animals infected with *T. rhodesiense* was shorter. The period between the crests of the graph in both strains was longer than in rats, namely, 5 to 8 days. (9) Rabbits inoculated with *T. rhodesiense* also exhibit periodic variation. (10) The periodicity is explained by (*a*) variations in resistance on the part of the host, accompanied by (*b*) the formation of latent bodies by the trypanosomes in the internal organs of the host during fall in numbers of the parasites in the peripheral blood.—Dr. H. B. **Fantham**: The life-history of *Trypanosoma gambiense* and *Trypanosoma rhodesiense* as seen in rats and guinea-pigs. (1) The researches were undertaken to investigate the parasitological aspect of the numerical cyclical development found by R. Ross and D. Thomson in the trypanosome of a patient suffering from sleeping sickness contracted in Rhodesia. Rats and guinea-pigs inoculated with *T. rhodesiense* and with *T. gambiense* were killed at various stages of infection and their internal organs examined, controls being used. (2) The formation of a non-flagellate, latent or rounded body from a trypanosome was observed in life, much of the cytoplasm and the flagellum of the flagellate being cast off. (3) Non-flagellate bodies were seen to grow into flagellate trypanosomes when placed in fresh, warm, uninfected blood. (4) The latent or non-flagellate stages are formed at or near the time when the trypanosomes are most numerous in the peripheral blood. (5) The latent bodies are relatively numerous in the internal organs when the flagellates are few in the peripheral blood of the host. (6) The formation of latent bodies takes place especially in the lungs. The latent bodies collect in the spleen and bone-marrow, as stated by Salvin-Moore and Breinl. (7) Latent bodies from the spleen of an infected rat inoculated into another rat produced trypanosomiasis. (8) The latent bodies are the post-flagellate stages of one generation of trypanosomes and the pre-flagellate stages of the succeeding generation. (9) There is a life-cycle of *T. gambiense* and of *T. rhodesiense* in vertebrate hosts. (Compare Crithidia and Herpetomonas in invertebrates.) (10) The occurrence of latent bodies explains the recurrence of trypanosomiasis in hosts when it has apparently died out. (11) Mutual action and reaction of the host and the parasite lead to the formation of rounded bodies, which are relatively resistant. (12) Some flagellate trypanosomes do not form latent bodies, but degenerate. Some latent bodies die, and do not flagellate.—Major R. **Ross** and J. G. **Thomson**: Experiments on the treatment of animals infected with trypanosomes by means of atoxyl, vaccines, cold, X-rays, and leucocytic extract; enumerative methods employed. In all the animals used in these experiments regular daily counts were made of the parasites in the peripheral blood by means of thick-film method. (1) Small repeated doses of atoxyl prolonged the lives of rats infected with the Rhodesian strain of trypanosomes, but failed to have any trypanocidal action, as was demonstrated by the fact that the parasites increased rapidly and showed very active division. (2) We venture to suggest that small doses of atoxyl actually stimulated the trypanosomes of this strain to divide, and that the drug is also a tonic to the body cells of the host. (3) Large doses of atoxyl are trypanocidal, but the parasites form resistant bodies, and cure is only temporary. The dose required to approach as near lethal as possible, and even then a cure was not obtained in the Rhodesian strain. (4) Vaccine treatment gave indefinite results, and insufficient experiments prevent definite conclusions being formed. The life of one rat seemed to be prolonged when the vaccine was administered in doses of 10,000,000 trypanosomes, with an interval between the doses. We suggest that the time of administration, the amount given, and the interval between the doses are all of importance, and further work is being carried out. (5) Animals suffering from trypanosomiasis had the incubation period delayed and their lives prolonged in the cold. (6) X-rays had no trypanocidal action, but the life of the animal may have been prolonged. (7) Leucocytic extract gave indefinite results.—A. **Campbell** and D. W. **Dye**: Sound vibrations of very high frequency produced by electric sparks.

Geological Society, December 7.—Prof. W. W. Watts, F.R.S., president, in the chair.—Dr. A. S. **Woodward**: Recent excavations in the cavern of La Cotte, St. Brelade's Bay (Jersey), made during the present year by the Jersey Society of Antiquaries. According to the report of Mr. E. T. Nicolle and Mr. J. Sinel, shortly to be published by the Jersey Society, the cave has yielded evidence of human habitation and traces of Pleistocene Mammalia. About a hundred flint implements of the Mousterian type have been obtained, besides part of a molar of *Rhinoceros antiquitatis*, and both teeth and antlers of *Rangifer tarandus*. Human remains and teeth of Bos have also been examined and determined by Dr. C. W. Andrews and Dr. A. S. Woodward, to whom the whole of the collection of mammalian remains was referred. This being the first discovery of typical Pleistocene Mammalia in the Channel Islands, the Jersey Society hopes to proceed with the excavations as soon as possible.—Dr. A. **Strahan**: The occurrence of recent shelly Boulder-clay and other glacial phenomena in Spitsbergen.

CAMBRIDGE.

Philosophical Society, November 28.—Sir George Darwin, president, in the chair.—Prof. **Pope**: Demonstration of natural colour photography of interference figures.—Dr. **Fenton** and W. A. R. **Wilks**: (1) Colloidal form of Nastvogel's osazone; (2) a method of characterising certain ureides.—H. O. **Jones** and D. I. **James**: The racemisation of malic and tartaric acids by heat.—Miss A. **Homer**: A note on the action of aluminium chloride on benzene.—Dr. **Forsyth**: Some theorems concerning uniform functions of two complex variables, together with some simple properties of such functions.—Dr. **Young**: Note on the fundamental theorem of integration.—H. C. **Pocklington**: (1) The determination of the exponent to which a number belongs, the practical solution of certain congruences, and the law of quadratic reciprocity; (2) the divisors of certain arithmetical forms, the primes of certain forms, and the arrangement of quadratic and some other residues.—L. **Doncaster**: Note on spermatogenesis of *Abraxas grossulariata*.—F. **Horton**: The discharge of positive electricity from sodium phosphate heated in different gases. A strip of platinum foil was covered with sodium phosphate and heated in a partial vacuum by means of an electric current. The positive leak from the heated strip to two parallel platinum plates, one on either side of it, was measured, when the following gases were, in turn, contained by the apparatus:—air, oxygen, carbon monoxide, hydrogen. It was found that the positive leak in oxygen was about the same magnitude as the leak in air. In carbon monoxide gas the leak was several times greater than the leak with the strip at the same temperature in oxygen or air at the same pressure. In hydrogen the leak was irregular, being when first tested about ten times as great as in carbon monoxide, but after heating for some hours it had diminished to less than the value in carbon monoxide under the same conditions. The fact that the positive leak is increased by admitting carbon monoxide into the apparatus is in accordance with the view that the positive ions from heated solids consist of molecules of this gas.—J. A. **Crowther**: The distribution of secondary Röntgen radiation round a radiator. The distribution of the secondary rays round a radiator under the action of a beam of primary Röntgen rays has been measured both for the "scattered" and for the "homogeneous" secondary rays. The scattered radiation rises to a maximum on both sides of the radiator in the line of the incident beam, and falls to a minimum at right angles to that direction. The maximum in the forward direction of the primary beam is considerably greater than that in the reverse direction. The homogeneous secondary rays are uniformly distributed round the radiator.—J. **Satterly**: The radium content of salts of potassium. Three years ago Campbell and Wood discovered that the salts of potassium were radio-active, giving off β rays. They tested the salts for radium and found none. In the opinion of the author their test was not as accurate as the occasion demanded, and he has performed some experiments in which the presence of radium in potassium salts is decisively proved. The amount, however, is extremely small (3×10^{-14} gm. radium per gm. of potassium salt), and does not interfere with Campbell and Wood's deductions.

EDINBURGH.

Royal Society, December 5.—Dr. Burgess, vice-president, in the chair.—E. M. **Wedderburn**: Temperature observations in the Madüsee (Pomerania), with mathematical discussion of temperature oscillations. A joint expedition with Prof. Halbfass, of Jena, was made in August to the Madüsee, a lake 17 km. long and 43 metres deep. About 3000 observations were made, and a temperature oscillation (or seiche) with a period of about twenty-five hours was observed, the oscillations at the two ends of the lake being in opposite phase. In the mathematical discussion of the oscillations of the bottom water in a lake of varying depth and breadth, the assumption was made that at a certain depth there was a sudden change of temperature, and therefore of density, and that the temperature was constant throughout each of the layers separated by this surface of temperature discontinuity. The period of the temperature oscillations depends on the differential equation

$$\frac{d^2P}{dv^2}+\frac{n^2}{g(\rho-\rho')\Sigma(v)}P=0,$$

where $v=\int b(x)dx$, $b(x)$ being the breadth of the surface of temperature discontinuity at a distance x from the origin taken in that surface; P is a function of v alone; ρ' and ρ are the densities of the upper and lower layers; and

$$\Sigma v = b(x)\Big/\left\{\frac{\rho}{A(x)}+\frac{\rho'}{A'(x)}\right\},$$

where $A'(x)$ and $A(x)$ are the areas of cross-section of the upper and lower layers. The equation is of exactly the same form as that used by Chrystal in his discussion of ordinary seiches. The period of temperature oscillation in the Madüsee, calculated according to this formula, is 24·9.—E. M. **Wedderburn** and A. M. **Williams**: Experimental verification of the hydrodynamical theory of temperature seiches. To verify the theory given in the last paper, laboratory experiments were made with a small trough of rectangular cross-section and parabolic longitudinal section. Paraffin oil represented the upper layer of warm water, and water the lower layer of cold water. The observed periods of oscillation in the lower liquid agreed well with calculation from theory. In some experiments the ends of the trough were truncated just above the surface of separation. As was anticipated by theory, this caused no appreciable alteration in the period of oscillation of the lower liquid.—Dr. Sutherland **Simpson**: Observations on the body temperature of the domestic fowl during incubation. The rectal temperature of the brooding hen was compared with the corresponding temperatures of a non-brooding or control hen. The modifications which were observed to occur during the brooding until a few days after the hatching were such as might be expected to occur because of the altered habits of the hen, apart altogether from the brooding condition.

PARIS.

Academy of Sciences, December 12.—M. Émile Picard in the chair.—W. **Kilian** and M. **Gignoux**: The fluvioglacial terraces of Bièvre and Basse-Isère. In a previous paper an account has been given of the pebble beds and terraces in the neighbourhood of La Valloire and Saint-Rambert-d'Albon. The present paper deals with the continuation of these beds towards the east, and leads to conclusions differing from the views now held as regards the relations of the external moraines with the terraces.—M. **Amann** and Cl. **Rozet**: The total eclipse of the moon of November 16, 1910, observed at Aosta, Italy. The contacts were observed under good conditions, the times of the two observers being concordant.—M. **Borrelly**: Observation of the Faye-Cerulli comet made at the Observatory of Marseilles with the comet finder. Positions of the comet and comparison stars are given for November 22, 23, and 26, and December 1 and 2. The comet appeared to be between the eleventh and twelfth

magnitude.—M. **Esmiol**: Observations of the comet 1910*e* (Faye-Cerulli) made at the Observatory of Marseilles with the Eichens equatorial of 26-cm. aperture. Positions given for December 1 and 2.—Maurice **Servant**: Transformations of surfaces applicable to surfaces of the second degree.—E. **Blutel**: The application of Newton's method of approximation to the approximate resolution of equations with several unknowns.—Léon **Autonne**: Commutative groups of hypercomplex quantities.—M. **Galbrun**: The asymptotic representation of the solutions of an equation of finite differences for large values of the variable.—W. **Stekloff**: The conditions of closing of systems of orthogonal functions.—H. **Violette**, E. **Lacour**, and Ch. **Florian**: Telescopic sights for marine guns of small calibre.—Georges **Claude**: Luminescent tubes containing neon. Photometric measurements have been made with a tube containing neon, 6 metres in length and 45 mm. diameter. Traces of impurities in the neon were found to be very prejudicial, and details of the method of purification found to be necessary are given. The efficiency was found to be 0·8 watt per candle, but this efficiency can be raised by increasing the length of the tubes, and reasons are given for hoping that about 0·5 watt per candle can be ultimately obtained.—G. **Massol**: The chemical composition of the gases spontaneously given off by the thermo-mineral spring of Uriage, Isère. The gas contains 1·87 per cent. by volume of rare gases, about one half of which is helium. From an estimate of the total gas evolved from the spring, it is concluded that not less than 20 litres of helium per day could be obtained from this spring.—Léon **Guillet**: The softening of metals after wire-drawing. Specimens of nickel and steel drawn into wires have been studied from the point of view of the annealing temperature.—E. **Léger**: The action of nitric acid upon the aloins: the production of tetranitroaloemodine and trinitro-2 : 4 : 6-meta-oxybenzoic acid.—Marcel **Godchot**: Hexahydro-acetophenone and hexahydrobenzoylacetone. Hexahydro-acetophenone on oxidation with alkaline permanganate gives adipic acid; the preparation of the oxime of this ketone and of hexahydroacetanilide are also described.—Paul **Gaubert**: The influence of foreign substances dissolved in the mother liquor on the facies of crystals of meconic acid and on their pseudopolychroism.—Louis **Duparc** and Georges **Pamphil**: Issite, a new rock in dunite. Issites are holocrystalline amphibole rocks of variable grain. Five complete analyses are given.—J. **Couyat**: Sodium rocks of the Arabian desert.—Ch. **Mauguin**: Doubly refracting liquids of helicoidal structure.—V. **Vermorel** and E. **Dantony**: General principles which ought to be followed in establishing formulæ for insecticides. It is shown that the quantities of soap used in insecticidal preparations can be reduced from 5 per cent. to 1 in 1000 without the moistening powers of the solution being adversely affected. Methods have been worked out for the employment of sulphur in such solutions.—L. **Moreau** and E. **Vinet**: Lead arsenate in viticulture and its distribution on the fresh and dried grapes. If the treatment is applied before flowering there is no danger of contamination by arsenic; if the application is delayed until after flowering, traces of lead arsenate are present on the grape.—MM. **Griffon** and **Maublanc**: A parasitic disease of the chestnut.—A. **Brissemoret** and A. **Joanin**: Contribution to the study of the physiological action of the organic bases. The sleep which is produced in the dog by the administration of conicine is due to the hydrocarbon residue in the base. Phenomena of narcosis analogous to those produced in the rabbit by morphine can be obtained by the action of hexahydrophenanthrene.—J. Künckel **d'Herculais**: The relation between the insects (Lepidoptera) and the flowers of the Zingiberaceæ, and in particular with those of Hedychium. Their capture, its mechanism, and its consequences.—M. **Roubaud**: Details concerning the morphological phenomena of the development of trypanosomes in Glossina.—E. **Sollaud**: The affinities of the genera Urocaris and Palæmonella.—Gabriel **Bertrand**: Observations on a note relating to the action of the Bulgarian ferment on proteid materials. Criticisms of a recent note by M. Effront.—Jean **Boussac**: The phenomena of folding in the Italian maritime Alps and at Castelvecchio.

VICTORIA.

Royal Society, November 10.—Prof. E. W. Skeats in the chair.—H. R. **Hamley** and A. L. **Rossiter**: The magnetic properties of "Stalloy." As the result of a research by (*a*) direct current, (*b*) alternating currents of different frequency, the authors conclude that, previous to annealing, "Stalloy" is of very little use, but that when annealed it furnishes an almost ideal material for the construction of electric machinery.—W. **Stapley**: The morphology of the vermiform appendix. The formation of a true appendix is shown to be due, not to the presence of lymphoid tissue, but to an atrophy of a larger cæcum, the peculiar shape and position being due to the disposition of the longitudinal bands.—William **MacKenzie**: Some observations on the comparative anatomy of the fibula. The fibula is held to be undergoing recession among the higher mammals, its future complete loss being indicated by the occurrence of congenital cases of absence of fibula in man. This loss is considered to be due to the assumption of the erect position.—Hilda **Kincaid**: The bio-chemical significance of phosphorus. Imported grasses and cereals have a lower phosphorus content than the same species grown in Europe, but a higher phosphorus content than native Australian plants. Victorian soils are poor in phosphorus. Animal tissues, eggs, and milk in Australia have a phosphorus percentage equal to the European. The export of phosphorus in the form of animal carcases is considerable.

THURSDAY, DECEMBER 29, 1910.

MALARIA PREVENTION.

The Prevention of Malaria. By Major Ronald Ross, C.B., F.R.S. With contributions by Prof. L. O. Howard and others. Pp. xx+669. (London: John Murray, 1910.) Price 21*s.* net.

FEW if any subjects bearing on the prosperity of tropical lands can be of greater importance than the effective control of those tropical diseases which have often proved barriers, sometimes insuperable, to their development. This will readily be admitted with reference to the colonisation of such lands by white men, but it is of at least equal importance for the welfare of the indigenous races the progress of which towards a higher civilisation is most intimately bound up with an increased immunity from disease and a higher standard of hygienic environment.

Of all the diseases prevalent in tropical and subtropical countries there is none to compare with malaria, either in point of view of frequency or of disastrous results in respect of the general health of a population. This has been acknowledged to a certain extent from the earliest times, but it has been left for modern science to demonstrate the true magnitude of the problem and to point out scientific and practical measures by which the damage caused by malaria may be controlled.

In this volume, by Major Ronald Ross, we have an admirable account of the whole of the many-sided problem of malaria prevention, stated in clear and eloquent fashion, and developing the subject in so logical a sequence that the reader is carried in complete sympathy with the author towards an acceptance of the preventive measures which he advocates as being the best at present available.

No one has better right to speak with authority on every branch of the subject than the author, whose discovery of the mosquito transmission of the disease laid the foundation for the majority of the preventive measures which have already been of inestimable service to humanity. The discovery of the malarial parasite by Laveran, epoch-making as it was, in itself did little to help in the prevention of the disease, and only a knowledge of the complete life-history of the parasite could teach us where and how to apply measures directed towards the prevention of this scourge of humanity.

Since this knowledge became available, numerous books have appeared, in many tongues, dealing with prevention, but the immense majority of these are either purely technical or purely popular, and there was a distinct place for a volume such as this, which, while avoiding unnecessary technical and medical detail, deals with each branch of the subject in comprehensive fashion and affords such a complete guide as is imperatively needed by all who have to deal with the subject practically, whether from the point of view of the health officer or from that of the civil administrator of a country or district. To obtain success in a malaria campaign it is not enough to be told what to do, one ought to know in addition the "why" of each step.

Throughout the whole of the work the author speaks, as he obviously feels, strongly on the half-hearted manner in which preventive measures have been applied by many bodies in administrative control of various malarious countries. He acknowledges that in many instances the cause of this official indifference is apprehension of excessive expenditure, but he shows clearly that, even from this low point of view, a grudging expenditure is bad finance. Granted that the measures he so ably advocates are carried out with intelligence, and under continuous and proper supervision, few who follow his arguments and examples will differ from him that few items in a colonial budget would have been better expended.

After an interesting historical account of malaria, from the earliest classical allusions to the discovery of the parasites and of the mode of transmission by anopheline mosquitoes, a clear account is given of the fundamental observations and experiments which have led up to our present-day knowledge. Next follows a most interesting chapter on the parasitic invasion of man. This will be read with perhaps the greatest interest by those who have practical knowledge of the disease, since it is replete with information of the most valuable character on such points as the number of parasites which may be introduced by the mosquito, the number which must develop from those introduced before illness is produced in man, the period of incubation, the limitation of the invasion, &c. Even those who are familiar with most of the subject-matter here dealt with will find much to interest them, since there is scarcely a point discussed which has not a direct bearing upon the question of prevention.

Major Ross lays great stress upon the necessity for a more accurate study of the disease by exact quantitative methods, and his arguments and illustrations in connection with this point will find general acceptance. For instance, he advocates a more accurate study of the numbers and local distribution of the particular anopheline mosquitoes which are found to transmit malaria in a given locality, since, without such a foundation, it is not possible to judge with any degree of accuracy as to the effects of the measures which may have been adopted with a view to their destruction. Again, in assessing the value of different preventive measures, such as mosquito destruction, the systematic use of quinine or the protection of individuals by mosquito netting, an accurate measure of the amount of malaria present in a particular population is an essential preliminary. He devotes considerable space to the best means by which such estimations may be carried out, and discusses the relative value of estimates of the actual number of individuals who have parasites in their blood at a given time, the estimation of the number who show signs of present or recent infection by enlargement of the spleen, the constantly-sick-rate, the death-rate, &c. He concludes that the most generally useful of these is the spleen-rate, since an actual microscopical examination of the blood demands too great labour. In this connection a good example of his mathematical reasoning shows that in a quarter of an hour a careful microscopical examination of a sample of blood for

parasites will only have searched one-fiftieth of a cubic millimetre. Now, since this volume is only about 1/150,000,000 of the blood in a man's body, it follows that there is a considerable chance that not a single parasite might be detected, although the individual might have 150 million of them in his circulation at the time!

Major Ross's preference for the determination of the "spleen-rate" appears justifiable on grounds of expediency, but, although he points out most of the more obvious fallacies to be guarded against in making such estimations, he scarcely appears to attach sufficient importance to these. For instance, there is very little experience accumulated as to the length of time which some degree of splenic enlargement may persist after recovery, while the splenic enlargement caused by ankylostomiasis, as has recently been pointed out by Darling, would invalidate the tests in certain localities.

The section dealing with the laws which regulate the number of anophelines in a locality will be fascinating reading to all who have some practical knowledge of these pests, and is full of most suggestive matter, much of which will doubtless be put to the test by those who have opportunity. The problem of attempting the destruction or limitation of mosquito life, under conditions where extensive breeding places abound, and where the usual measures appear at first sight impracticable, are boldly faced, and those who are satisfied with Major Ross's mathematical demonstrations on such points as the variations of mosquito density due to various causes, the random scatter of mosquitoes from a given point, &c., will find it necessary to revise some views which have been and are extensively held on the impossibility of limiting the mosquito population in certain conditions.

The thoroughness with which the earlier portions of the book have dealt with all branches of the subject greatly adds to the value of the chapter dealing with the selection of the preventive measures to be made in a given instance, since one is able to follow the author in his clear exposition of the manner in which one must study the local conditions in every instance before deciding on the plan of campaign. As he is careful to point out, without such close study of these conditions a scheme might be drawn up which was foredoomed to failure, and large sums of money might uselessly be thrown away. The chapter abounds in valuable practical hints for the guidance of those responsible for the organisation of such campaigns, and it may also be studied with the greatest profit by laymen whose only desire is to know how best they, individually, may avoid infection on proceeding to a malarious country.

The second half of the book consists of a series of articles by well-known authorities dealing with experiences of individual malarial campaigns in many countries, and these afford a number of object-lessons in the application of the principles enunciated in the first half. There are altogether twenty-one contributors to this portion, and the majority are recognised authorities on the subject of malaria in the particular country dealt with. For instance, the campaign against malaria in Italy is from the pen of Prof. Celli, while that dealing with the most successful of all malarial campaigns, that in the Isthmus of Panama, has been written by Colonel Gorgas. Dr. Schilling deals with malaria in German possessions; and the measures employed in French territory are described by Dr. Edmond Sergent. The completeness of this portion of the book is indicated by the fact that it concludes with two most interesting articles on the prevention of malaria in troops in war and in peace, the former by Lieut.-Colonel C. H. Melville, and the latter by Major C. E. P. Fowler, who was associated with Major Ross in his campaign in Mauritius, to which so many allusions are made in the systematic portion.

Major Ross and his collaborators may be congratulated on having produced a work which will be of the highest value to all who are concerned with the future progress and welfare of our tropical possessions.

W. B. L.

THE BRITISH MUSEUM COLLECTION OF FOSSIL REPTILES.

(1) *A Descriptive Catalogue of the Marine Reptiles of the Oxford Clay, based on the Leeds Collection in the British Museum (Natural History), London.* Part i. By Dr. C. W. Andrews, F.R.S. Pp. xxiii+205+x plates. (London: Printed by order of the Trustees of the British Museum, 1910. Sold by Longmans and Co., B. Quaritch, and Dulau and Co., Ltd.) Price 25*s*.

(2) *A Guide to the Fossil Reptiles, Amphibians, and Fishes in the Department of Geology and Palaeontology in the British Museum (Natural History).* Ninth edition. Pp. xviii+110. (London: Printed by order of the Trustees of the British Museum, 1910.) Price 9*d*.

(1) THE museum having acquired the unrivalled collection of reptilian remains obtained with much labour and unceasing care by the Messrs. Leeds—more especially Mr. A. N. Leeds—from the brick-pits in the Oxford Clay near Peterborough, it was only fitting that they should be described in a manner worthy of their importance and value. So far as the marine forms are concerned, that is to say, the ichthyosaurs, plesiosaurs and pliosaurs, and crocodiles, the task has been entrusted to Dr. C. W. Andrews, who for several years past has devoted a large portion of his time to the study of these groups. How thoroughly well he has accomplished the work will be apparent to all specialists who study the present volume, which deals with the ichthyosaurs and plesiosaurs.

The work appeals, however, to other than specialists, for it not only serves to make known the remarkably fine state of preservation in which many of the skeletons of these strange reptiles are found, but it also contains a number of interesting observations with regard to their probable mode of life and the conditions in which they existed. So nearly complete, indeed, are many of the skeletons, that not only has it been found possible to mount several for public exhibi-

tion, but, owing to the separation of their constituent elements, the details of the osteology can be studied, except in the case of the skull, which is often badly crushed, as if they belonged to modern reptiles. It should be added that this full acquaintance with the osteology of these saurians is largely due to the extreme care exercised by Mr. Leeds in extracting them from the matrix.

The remains are generally supposed to have been laid down in rather deep water, but the association of the marine forms with terrestrial dinosaurs, and perhaps also the occurrence of masses of lignite, suggests that the deposit was formed near a coast, and not improbably represents the mud-banks in the delta of a mighty river. Here Ophthalmosaurus, the single and most highly specialised representative of the ichthyosaurs, with its powerful caudal fin, pointed head, enormous eye, and porpoise-like body, probably lived in the open sea, where it played the part now assumed by whales and grampuses. Why this particular type should have become practically edentulous, whereas its upper Cretaceous successors were remarkable for their powerful dentition, is somewhat difficult to understand, although, as Dr. Andrews suggests, this feature was probably connected with the nature of its food. Certain features in its organisation suggest that it was capable of "sounding" to considerable depths.

In marked contrast to the movements of this ichthyosaur were those of the contemporary plesiosaurs, which were far more specialised types than their forerunners of the Lias. Instead of being driven through the water by the screw-like action of a powerful tail-fin, these appear to have rowed themselves on or near the surface by means of their strong paddles, of which the hind pair was nearly equal in capacity to those in front, whereas the tail was short, and provided, at most, with a rudimentary fin. Their whole organisation indicates that they haunted the neighbourhood of the coasts, whereas their short-necked and more strongly built relatives the pliosaurs may be assumed to have ventured further out to sea, although they did not possess the truly pelagic habits of the whale-like ophthalmosaur. The littoral habits of the plesiosaurs exposed them to much more varied conditions of life than was the case with the last-named reptile; and it was these diverse conditions which probably led to the differentiation of the group into the numerous types so well described in the volume before us.

To follow the author through his survey of the osteology of the groups forming the subject of this volume would demand much greater space than the editor is disposed to grant. Attention may, however, be directed to the figure on p. 12 illustrating the form and arrangement of the constituent bones of the occipital region of the ophthalmosaurian skull, and more especially to the remarkable position and relations of the opisthotic and stapes. The great length of the parasphenoid element (p. 15) is also noteworthy, while of even greater interest is the author's reference of the ichthyosaurian humerus to its proper side of the body (p. 52). Among the plesiosaurs it must suffice to refer to the determination of the relations and form of the clavicles and interclavicles, and especially the gradual waning of the latter (compare Figs. 61, 62, 70, 88).

Dr. Andrews has a good deal to say as to the phylogeny of the ichthyosaurs, for which readers must refer to the work itself; that of the plesiosaurs and pliosaurs is reserved for the second volume, which we hope to welcome before many months are past.

(2) Passing on to the guide-book to the fossil reptile and fish galleries, the mere fact that a new edition has become necessary after the lapse of only five years from the issue of its predecessor (which was entirely re-written), affords sufficient evidence that the work meets the requirements of the class of visitors for whom it is intended. As we are told in the preface, the new edition is practically a replica of the eighth issue, and therefore demands no special notice in this place. It may be noticed, however, that the price has been raised from sixpence to ninepence, at which figure the work is still a marvel of cheapness. In the next edition it might be well to explain the meaning of "type" specimens (*vide* preface), of which the general public has no conception, and likewise to amend the legend to Fig. 39, which states that the specimen belongs to a small tortoise, whereas it is really something like twenty inches in length.

R. L.

ELECTRO-CARDIOGRAMS.

Das Elektrokardiogramm des gesunden and kranken Menschen. By Prof. Friedrich Kraus and Prof. Georg Nicolai. Pp. xxii+322. (Leipzig: Veit and Co., 1910.) Price 12 marks.

THE electrical phenomena of the living heart has been a fascinating study among physiologists since the early days of electro-physiology; information has been gathered with greater and greater accuracy as apparatus and methods of investigation became more and more refined, and now the registration of the electrical changes in the heart may be, and is, practically employed in the diagnosis of heart affections in the wards of the hospital. A full discussion of the origin and progress of method in this direction is given in this book, which has been produced by authors well acquainted practically with all the details of this branch of physiological and clinical inquiry. The progress of research is strikingly shown in a bibliography at the beginning of the work containing a list of 243 papers on the subject, of which no fewer than 131 have appeared since the beginning of 1900.

It is interesting to notice that investigations into the electrical phenomena of the heart are associated at different periods with the invention of special instruments and methods, such as the galvanometers of Matteucci and du Bois Reymond, the differential rheotome of Bernstein, the capillary electrometer of Lippmann, and, still more recently, the string galvanometer of Einthoven. Matteucci, in 1843, was the earliest observer with the galvanometer; then, in 1849, followed du Bois Reymond with his bussole; Köllker

and Müller worked about 1856, Donders about 1872; and at last there were the elaborate researches of Engelmann from 1873 to 1877. Gotch and Burdon Sanderson studied the phenomena of inhibition in the heart of the tortoise in 1877; Bernstein, du Bois Reymond, Engelmann, Hermann, and Burdon Sanderson used the rheotome between 1868 and 1887. Then followed the invention of the capillary electrometer by Lippmann in 1873; it was soon used by Engelmann and Marey, and in 1883 it was employed in research by Burdon Sanderson and Page. Waller, in 1889, was the first to employ the instrument in the investigation of the human heart. The actual oscillations in the tube of the capillary electrometer were photographed on a rapidly moving plate, so as to produce a cardiogram, and with this invention the names of Burch and Burdon Sanderson will be always associated (1890). In more recent times we have the invention of the string galvanometer by Ader in 1897, and perfected by Einthoven, until it must be regarded as by far the most sensitive instrument for the purpose. The instrument, as now constructed, is much more delicate than the original instrument of Ader, while the apparatus had been made complete by the photographic registering apparatus made by various ingenious workers in optics and mechanics.

The accurate interpretation of the electro-cardiogram owes much to Waller, who established important leading principles on which monophasic and diphasic currents can be explained. He also gave a schematic representation of the action currents that can be led off from the living human heart (Fig. 16, p. 45). In the work under notice, there is a full description of the principle and mechanism of the string galvanometer, and an analysis of the curves produced from it (p. 64). The introduction of the quartz fibre has most materially increased the delicacy of the instrument. There can be no doubt that only an expert can use the instrument in a satisfactory manner, as is well illustrated by a study of the diagram of the apparatus in an actual experiment in Fig. 28, p. 89. This method is much more complicated than the simple galvanometer experiments once in vogue in every physiological class-room or laboratory.

Kraus and Nicolai then give a thorough analysis of the electrocardiogram, showing in the diphasic effects groups of electrical oscillations in the curve which are associated with the contractions of the auricle, with those of the ventricle, and with changes occurring also during the diastole of the ventricles and the filling of the auricles. The time relations of all those phenomena can also be accurately determined; indeed, an insight is obtained into the phenomena of the living beating human heart not otherwise possible. They also endeavour to show that those phenomena may be explained or accounted for by our knowledge of the muscular arrangements of the walls of the heart. Without mentioning the old researches of Borelli or the more recent dissections of Pettigrew (to be seen in the museum of the Royal College of Surgeons, Lincoln's Inn Fields), they describe the spiral arrangement of the fibres, the relation of many of the fibres to the papillary muscles, the fibres of Wenckebach (1901) between vena cava and the auricle, and the bundle of His (1893) between auricle and ventricle. Nearly thirty years ago there appeared the classical research of Gaskell (1883) on the heart of the tortoise, which showed the passage of impulses from auricle to ventricle, and was the beginning of much work of great clinical as well as physiological importance. The analysis of many electrocardiograms is given with great care and thoroughness by the authors in chapters vi. to x., and to those the reader must be referred.

The second portion of the work relates to the clinical use of the string galvanometer in the investigation of diseases of the heart and of the circulation. When one considers that the complete apparatus costs from 200*l.* to 250*l.*, and that a special knowledge of electrical appliances is required, it will be evident that the method cannot be expected to come into general use, even in the wards of a well-appointed hospital. Physicians will depend more on mechanical appliances for registering the movements of the various pulses (both venous and arterial) and of the heart itself, a method of sphygmographic investigation that has received a new lease of life by the labours of Mackenzie and others. At the same time it must be admitted that the electrical phenomena give a glimpse of phenomena actually happening in the heart which would escape detection by the mechanical method, as, for example, slight changes in the beat of the auricles, and some phenomena which may account for want of rhthym, as when the auricles and ventricles do not beat in the normal consecutive order. The time relations can also be accurately noted. The authors give many cardiograms well worthy of the study of physicians. These must not be confounded with the tracings that, by other methods, may be obtained of the vibrations of the sounds of the heart. Science must advance, but it is rather disheartening to be obliged to take the view that these elaborate researches have very little to do with the actual treatment of diseases of the heart, and the sufferer whose heart is beating arhthymically will find cold comfort in the certain knowledge that there is some kind of fatty or other degeneration in the fibres of the bundle of His in his cardiac organ.

Since the above was written a valuable paper has appeared in *Heart* by Dr. Thomas Lewis and B. S. and Adele Oppenheimer on "The Site of Origin of the Mammalian Heart Beat; the Pace-maker in the Dog." The researches have been carried out with the string galvanometer, with special reference to the electrical relations of the collection of specialised tissue at the upper caval end of the sulcus terminalis of His. The tissue, or node, as it may be termed, was discovered by Keith and Flack. Dr. Lewis and his co-workers find electrical evidence to show that it is the site of primary activity, that is to say, from it impulses radiate that are the cause of the co-ordinated heart beat. This result, long sought for by other observers, is an important addition to cardiac physiology, while it illustrates the value of the use of the string galvanometer.

JOHN G. MCKENDRICK.

AUSTRALIAN TRIBES.

(1) *The Tribe, and Intertribal Relations in Australia.* By G. C. Wheeler. With a prefatory note by Prof. Edward A. Westermarck. Pp. xii+168. (London: J. Murray, 1910.) Price 3*s.* 6*d.* net.

(2) *Two Representative Tribes of Queensland, with an Inquiry concerning the Origin of the Australian Race.* By J. Mathew. With an introduction by Prof. A. H. Keane. Pp. xxiii+256. (London: T. Fisher Unwin, 1910.) Price 5*s.* net.

ACQUAINTANCE with the interesting political and social organisation of the Australian aborigines has gradually destroyed the tradition of their primæval simplicity, and the information collected and classified by Mr. Wheeler (1), during his work as Martin-White student of sociology in London University, shows that intertribal relationships in Australia are unusually well regulated. Mr. Wheeler declares that "in contrast with the loose ideas generally held war in these tribes cannot be deemed a normal condition," and Prof. Westermarck, in a prefatory note, remarks "among the Australian aborigines the germs of international law" and "something like an anticipation of the Geneva Convention." Instead of the Australian aborigines retaining a primitive communism, territorial ownership is so fully recognised that, according to Mr. Wheeler (p. 161), "War has no other purpose than the seeking of justice or revenge for injuries done." War there, he says, is never for the sake of territorial conquest, as the right of the lawful owners of land is regarded as absolute.

The main purpose of Mr. Wheeler's study is to collect the available information as to the relationships of the Australian tribes. He summarises the evidence as to their confederations, the rights of territorial sovereignty, the regulations which govern tribal intercourse—including barter, asylum, and the safety of envoys, the punishment of offenders belonging to different tribes, and war. The essay is a discussion of second-hand evidence, in the valuation of which the author is perhaps not always successful. Thus, he disparages Howitt's work, since, as that author carefully explained the source of his information, it is obvious how much of it came from others; but Mr. Wheeler is less cautious in regard to some authorities, in whose writings observation and inference are less easily distinguished.

The essential difficulty in the study of intertribal relationships among the Australians is the absence of any trustworthy distinction between tribes and intertribal local groups, and between tribes and "nations." Mr. Wheeler uses the term nation occasionally, but regards it as inappropriate in Australia, as the groups are so indefinite. He admits that there is no firm line to be drawn between nations made up of tribes, and tribes made up of local groups; and he recognises that the relations between local groups of the same tribe do not differ from those of local groups belonging to different tribes. The intertribal regulations, which Mr. Wheeler's study shows are so widely recognised in Australia, therefore deal with the relations of local groups, which have been perhaps only recently and temporarily isolated or combined, and not of tribes separated by racial differences, as in India or Africa, or by traditional feuds, as in North America.

According to Mr. Wheeler, the best test of a tribe (p. 55) is that the intertribal groups do not carry on unregulated warfare, and during warfare do not eat the dead. According to Mr. Mathew, on the other hand, tribal distinctions are based on language.

(2) Mr. Mathew's book may be divided into two distinct sections. Its main value is an account of the Kabi and Wakka tribes, who inhabited the basins of the Mary River and upper Burnett River in southern Queensland. The author had excellent opportunities for the study of the Kabi, as he lived among them from 1866 to 1872, and has re-visited them in 1884 and 1906. He knows their language and appears carefully to have observed their habits and collected their beliefs and folklore. Mr. Mathew's most interesting chapter is upon religion and magic. He concludes that "these tribes possessed the elementary contents of religion" (p. 168), and had some belief in supernatural beings, of whom they spoke with reverence and of whom the "great supernatural" was nameless and was referred to only with bated breath.

The value of Mr. Mathew's book is reduced by his constant re-statement of the theory which he advanced in 1899, in his "Eaglehawk and Crow," and in an earlier paper. He there claimed that the two totemic divisions named after the Eaglehawk and Crow were due to racial differences; he believed that the Australian aborigines have originated from the fusion of a dark "Papuasian" people, who were of the same race as the Tasmanians, with a fairer people who were possibly connected with the Dravidians of India, the Veddas of Ceylon, and the Toalas of Celebes. He re-states this view in an introductory memoir, and repeats it, but without mentioning the strongest objections to it, and still claiming in its support authors, such as Lydekker—who has long since abandoned it. Mr. Mathew admits that some tribes outside Australia are also divided into two exogamous classes, and he appears disposed (p. 140) to extend his racial theory to those cases. Moreover, many Australian tribes are divided into four classes instead of into two, and as Mr. Mathew admits that the fourfold division is not racial, it seems unnecessary to adopt his explanation for the division of the tribes into two classes. Mr. Mathew states that the light-blooded and dark-blooded sections may still be recognised among the Australians; but, in quoting one of these cases he admits (p. 142) that his informants differed as to which section was the light and which the dark. The difference in colour appears to be as slight as the rest of the evidence in favour of Mr. Mathew's theory. The account of the Kabi is, however, a useful contribution to Australian anthropology.

SOME CRITICAL SPECIES OF VERONICA.

Veronica prostrata L., Teucrium L., und austriaca L. nebst einem anhang über deren nächste verwandte. By Dr. Bruno Watzl. (Abh. der K.K. Zool-Botan. Gesellschaft in Wien. Bd. v., Heft 5.) Pp. 94+Tafel xiv. (Jena: Gustav Fischer, 1910.) Price 7 marks.

DR. WATZL has made a detailed study of three closely-allied species in what is generally recognised as a very critical genus. Bentham, when mono-

graphing the family Scrophulariaceæ in De Candolle's Prodromus (1846), grouped these species with a few others as a subdivision Pentasepalæ of the section Chamædrys, characterised and distinguished from other subdivisions, and the majority of the species of the genus, by the five-toothed calyx as contrasted with the usual four-toothed organ. The disappearance, by gradual reduction, of the median sepal is one of the factors in the diminution of the zygomorphy, which is a feature of the Veronica flower when compared with the more strikingly zygomorphic forms typical of the family. These pentasepalous forms are to be regarded as an older type from which the more numerous tetrasepalous have been derived, and Dr. Watzl again directs attention to the fact that the character is a variable one, four-sepalled flowers being of frequent occurrence.

None of the three species which are the subject of the memoir occurs in the British Isles, but they are widely distributed in central and southern Europe. *Veronica prostrata* is the most constant of the three; besides the type only one form and one variety (from Siberia) are recognised. There is, however, a considerable amount of variation in habit, degree of hairiness, and size of parts; and, as shown by plate v., the leaf displays great variety in size and form in specimens from different localities. The other two species are remarkably polymorphic, and are subdivided by the writer into a series of subspecies, varieties, and forms, with, in several cases, a number of transitional forms between the different subspecies. Dr. Watzl has made a careful and exhaustive study of a large series of specimens from central and southern Europe, as well as of the citations in the numerous European floras, and the results of his work will have a special interest for the critical student of the European flora. It is inevitable, however, that the personal element should enter into such a detailed study of a highly variable species occurring over a somewhat extended area, and it is probable that other critical students of the same group would not entirely concur with the limitations of forms and varieties which are adopted by Dr. Watzl.

A. B. R.

SCHOOL DRAWING.

(1) *A Course of Drawing for the Standards. Being a Selection of Sheets from "A Complete Course of Free-Arm and Industrial Drawing."* By J. W. T. Vinall. Pp. 24+xxiv charts. (London: Blackie and Son, Ltd., 1910.) Price 6*s*. net.

(2) *Natural and Common Objects in Primary Drawing, with Full Directions as to Their Use. A Handbook for Teachers.* By J. W. T. Vinall. Pp. v+68. (London: Blackie and Son, Ltd., 1910.) Price 3*s*. 6*d*. net.

(1) THE issue of the author's "Complete Course of Free-Arm and Industrial Drawing," in sections is a wise step that will be much appreciated by teachers. The first portion, published as "A Course of Kindergarten Drawing, for Infants and Small Children," has now been followed by a second and more advanced selection under the title given above. It outlines a progressive school course for youths from six years upwards, corresponding to standards I. to VII. and beyond. The first six plates deal with brush work and the principles of colour harmony, with applications to natural objects and ornamental designs. The next six illustrate a well-graded course of free-arm drawing in coloured chalks, based on circular, elliptic, and compound curves. The applications to natural and familiar objects, to ornamental patterns and designs, with reference to the laws of growth, repetition, and radiation, are very numerous and intensely interesting. The remaining charts comprise free-hand drawing in pencil, crayon, and with the pen; further brush work and shading; and model and perspective drawing, with technical and other applications. The plates are accompanied by a very lucid and suggestive description that will prove most valuable to teachers. They are beautifully executed, generally in colours. As a whole, the work forms as admirable a course of school drawing as could be desired, and impresses the reader with the great educational value of training conducted on lines indicated by the author.

(2) This is a new work, intended to be supplementary to the one noticed above, its main object being to assist the teacher in the selection of objects, properly graded and suitable for class instruction in drawing in elementary schools. It is based on the syllabuses of the English and Scottish Boards of Education. The objects are displayed in a number of plates, to which teachers will often be glad to refer. The illustrations include familiar objects in common use, nature forms and specimens, subjects for measured drawings, and specimens of alphabets and printing. The plates are described in the text, and are preceded by a general discussion of the aims and qualifications of the teacher, of the apparatus used, and of the methods of work. The book can be recommended to teachers as affording valuable guidance in their work.

OUR BOOK SHELF.

Iron and Steel Analysis. Vol. i., Ordinary Constituents. By A. Campion. Pp. 80. (Glasgow: Fraser, Asher and Co., Ltd. 1910.)

THIS small handbook gives a detailed account of the methods used in determining the six or seven elements invariably occurring in pig-irons and ordinary steels, and also those employed in the proximate analysis of coal.

With few exceptions, one method only is described for each element, and in every case one which has been in use (with modifications) in steel-works' laboratories for many years. Although, therefore, there is nothing new by way of contribution to the existing literature on the subject, the book is eminently suited to beginners. It is doubtful, however, whether the author's hope that works chemists will find the book useful will be realised, as some of the methods described are by no means quick enough. Rapidity, consistent with accuracy, is a very important consideration in steel-works laboratories, a fact which the author obviously recognises in the preface.

The opening out of grey irons with hydrochloric acid in silicon determinations, as described in this

book, has been largely superseded by the more rapid and trustworthy process of Drown. The gravimetric methods described for manganese and phosphorus are cumbersome. In the case of the former, the importance of neutralising the acid solution of ferric and manganese chlorides at a boiling temperature is wrongly insisted upon, and the washing of the voluminous basic ferric acetate precipitate should have been avoided.

Manganese furnishes one of the cases in which alternative volumetric methods are described, the first of which is undoubtedly more accurate than the gravimetric method as carried out by the author. An alternative process, preferably volumetric, for the determination of phosphorus, would have materially increased the value of the book. The other elements, and particularly the most important one (carbon), are dealt with in a very satisfactory manner. F. I.

The Potter's Craft. A Practical Guide for the Studio and Workshop. By F. Binns. Pp. 171. (London: Constable and Co., Ltd., 1910.) Price 6s. net.

THE preface leads to great expectations, for the author says:—"This book is the outcome of an experience extending over a period of thirty-six years. Twenty years ago it would have been impossible for the science of ceramics was not then born." The book itself is, however, very disappointing, and cannot be considered as a serious contribution to ceramic science. It is written apparently for the amateur potter; it certainly would not be of use to anyone else, and there is nothing in it that was not known twenty years and more ago.

Much of the book is taken up with photographs and descriptions of two well-known processes, viz., "mould-making" and "throwing." These could be much better learnt and understood by a visit to a pottery; certainly no one will ever learn to be a craftsman by studying the book. When one knows the time it takes for a professional potter to learn to throw even simple small pieces to a given size, it seems almost ludicrous to write as the author does of an amateur making vases two or three feet high by doing the work in sections. The chapter on glazes and glazing can lead to nothing but disappointment.

It is hard to believe that the author has had great practical experience when we see him trying to deal with "the defects of glazes" in about two pages. For example, practical men know what a difficult problem "the pinholing of glazes" is, and how many and varied are the causes which produce it. Mr. Binns devotes two lines to it!—"Pinholes appear in the glaze when cool. Too rapid cooling is the cause." It is difficult to write with patience of this kind of treatment, particularly when we remember the preface.

Heroes of the Elizabethan Age. Stirring Records of the Intrepid Bravery and Boundless Resource of the Men of Queen Elizabeth's Reign. By E. Gilliat. (London: Seeley and Co., Ltd., 1911.) Price 5s.

THE stout-hearted men who sailed the seas in the days of England's awakening were indeed heroes. Their charts were made with the degrees of longitude at different latitudes of equal length; they were inaccurate even as regards the shores of the English Channel, for it is one of the claims to renown of John Davis that he surveyed the Channel coasts in addition to those of the Arctic, of Magellan Straits, and of the Scilly Isles. They dared to cross the Atlantic in ten-ton vessels, for the *Squirrel*, in which Sir Humphrey Gilbert was lost, was of this size; they took five months on the voyage to the Cape of Good Hope, and the chances were that disease alone would kill off a large proportion of the crew of every vessel which went on a protracted voyage.

Englishmen fitted out expedition after expedition; many times for no return, sometimes for a return of hundreds per cent. on their outlay, for the capture of one rich carrack might suffice to pay the cost of a large expedition. In this atmosphere Hawkins began the slave trade, Sir Richard Grenville fought his good fight off the Azores, and Howard and his captains harassed the Armada and made its efforts fruitless. In this spirit Sidney died at Zutphen. These heroic efforts form part of the great struggle for Protestantism which lies at the background of the life-story of the thirteen heroes as depicted in this splendid gift-book by a sometime master at Harrow School. Well illustrated and produced, this book will delight the heart of most boys and many girls, even those of somewhat mature age. B. C. W.

International Language and Science. Considerations on the Introduction of an International Language into Science. By Profs. L. Couturat, O. Jespersen, R. Lorenz, W. Ostwald, and L. Pfaundler. Translated by Prof. F. G. Donnan. Pp. ix+87. (London: Constable and Co., Ltd., 1910.) Price 2s. net.

Internaciona Matematikal Lexiko en Ido, Germana Angla, Franca e Italiana. by Dr. Louis Couturat. Pp. 36. (Jena: Gustav Fischer, 1910.) Price 1.50 marks.

THE first of these books is an English edition of a work the German edition of which was reviewed in NATURE for August 19, 1909. The translator is Prof. F. G. Donnan, of Liverpool University. The "Internaciona Matematikal Lexiko," by Dr. Louis Couturat, contains all the technical terms commonly used in mathematics. The language of the International Commission constitutes in many respects a great advance on its predecessors. If there is one feature that possibly calls for improvement, it is that the new language is not based on Latin as much as it might be, in view of the fact that Latin is taught in schools in every civilised country. By adopting the Latin vocabulary free from all unnecessary grammatical technicalities, the need of a new language could have largely been obviated. It is true that a large proportion of the words are taken from Latin, but there are exceptions, such as "lasta" for ultimate, "samcentra, sam-foka," and so forth, for concentric and confocal, "ringo" for annulus, and "helpanta" for auxiliary.

The Presentation of Reality. By Dr. Helen Wodehouse. Pp. x+163. (Cambridge: University Press, 1910.) Price 3s. net.

IN this little book Dr. Wodehouse (who is lecturer in philosophy in the University of Birmingham) attempts a description of knowledge from the point of view of a philosophical psychology. She avoids metaphysics as far as possible, but maintains that in all cognitive experience we come into immediate contact with objective reality, of the existence of which we have in experience an irrefutable witness, and that on all levels of cognition, sensuous or intellectual, this happens in the same way, namely, by the presentation of an object to a subject.

The author's metaphysical inclinations seem to be towards the school of Reid, while among recent writers her affinities are with Dr. James Ward, Dr. G. F. Stout, and Dr. A. Meinong. Bradley on the one hand, and James on the other, come in for acute criticism, Dr. Wodehouse believing strongly—as against the great pragmatist—that reality does not wait for our thinking to make it, though the discovery of reality does; that some discoveries can be made, and that it

is the duty of philosophers to go on trying to make them, with which, no doubt, both pragmatists and absolutists would agree. Indeed, "in spite of everything, this is presumably the real standpoint of all of us."

Lessons on Elementary Hygiene and Sanitation, with Special Reference to the Tropics. By W. T. Prout. Second edition, 1909. Pp. xx+159. (London: J. and A. Churchill, 1908.) Price 2s. 6d. net.

WE are not surprised that this little book has passed into a second edition. The plan of it is well conceived and the matter excellently written. It tells in the simplest language, with many appropriate comparisons which drive home the meaning, the structure of the body and its functions, how health may be safeguarded, and how disease is propagated. Disease germs, their mode of spread and entrance into the body, are explained, and the salient points with regard to the principal infective diseases are adequately considered. Being avowedly written for residents in the tropics, and in particular for those in Freetown, West Africa, diseases like malaria, cholera, plague, sleeping sickness, leprosy, &c., receive considerable attention, but otherwise the details given are equally applicable to the hygiene of any district.

Chapters on water supply and its purification, the dwelling and sewage removal, respiration and ventilation, diet and clothing are included, and render the book a complete popular exposition of the principles of hygiene. It is also well and sufficiently illustrated. R. T. H.

Aëroplane Patents. By Robt. M. Neilson. Pp. x+91. (London: Constable and Co., Ltd., 1910.) Price 4s. 6d. net.

THIS is a useful book, which may be recommended to all who are interested in the subject of aëronautics. It begins with thirteen pages of sound advice to inventors, and continues with a list and description of the various patents relating to heavier-than-air flying machines. The list does not profess to be complete or exhaustive, but it contains all the important patents and most of the minor ones are mentioned. The descriptions given are sufficient to explain the objects and claims made in each case.

The period covered by the list extends from 1860 to 1910, and perhaps the most interesting matter which it brings to our notice is the enormous increase in the number of patents relating to aëronautics taken out since 1907. From 1860 to 1906 the average number of patents was about six per year. In 1906 the number was 29; in 1907, 42; in 1908, 115; in 1909, 759; and in 1910 (for eight months), 412.

That but a small percentage of the patents should be of value is only what might be expected, but the total number is evidence of the attention which is being given to the subject.

Stray Leaves on Travel, Sport, Animals, and Kindred Subjects. By J. C. Walter. Pp. xii+295. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1910.) Price 5s. net.

THE ten chapters making up this book are for the most part extracts from the author's diaries written among the scenes described, and papers prepared for meetings of a natural history society.

The conversational style adopted makes reading easy, and the persevering reader will incidentally accumulate much useful information about the countries in which the author has travelled, and become acquainted with the habits of many animals which have aroused the author's interest. Mr. Walter's wanderings have by no means been confined to his own country; we have chapters dealing with his excursions in Egypt and Palestine, France, Switzerland, and Italy respectively. On each of his numerous journeys Mr. Walter was an industrious diarist.

1200 *Mining Examination Questions.* Arranged and compiled by G. L. Kerr. Pp. xxvii+111. (London: Crosby Lockwood and Son, 1911.) Price 2s. 6d. net.

THESE questions have been selected principally from the papers set at the examinations held in the different districts of Britain for managers' and under-managers' certificates. The volume also contains copies of ventilation plans set at these examinations, and suggestions to candidates who desire to qualify for mine managers' certificates.

To some of the questions answers have been given, but to the majority of them this has intentionally not been done. The compiler explains that the correct answer for any given question will vary somewhat according to the formula used, and in mining unfortunately no uniform set of formulæ has yet been accepted.

Chez les Français. Edited by H. Carter. With Exercises, by C. F. Shearson. Pp. vii+171+vii. (London: A. and C. Black, 1910.) Price 2s.

THIS well-selected collection of passages in French, from writers of recognised literary merit, dealing with France and French customs, should prove useful in classes where some progress has been made in the study of the language. The book should be particularly serviceable in connection with elementary geographical teaching.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Biological Inquiry into the Nature of Melanism in *Amphidasis betularia*, Linn.

IT is well known to entomologists that dark varieties of several species of moths have recently become increasingly common in many localities within the British Isles, and also that the dark forms are appearing in fresh districts.

It is very desirable and important to know whether the colour of these dark races of moths is protective or whether it has some other significance.

Before, however, any definite explanation of these phenomena can be attempted, it is necessary to have as complete a knowledge as possible of all the circumstances which are likely to have any influence on the species known to exhibit this melanic change. One significant point in connection with my inquiry concerns the resting habits of the moths which are subject to this melanic variation. For example, it is important to know whether the light-coloured moths (*i.e.* the peppered form of *Amphidasis betularia*) generally rest during the day on lichen-covered trunks of trees or any other light-coloured object, and also whether the dark insects (as the form Doubledayaria of *A. betularia*) select black tree trunks or other dark-coloured objects on which to rest.

Information of this nature can, however, be obtained only by the cooperation of very many entomologists, for the chance of obtaining sufficient evidence from the observations of one or two persons is very remote. I should therefore be extremely grateful if entomologists would assist me in collecting information regarding the resting habits of any of the undermentioned species belonging to the Geometræ which may have come under their notice:—

Amphidasis betularia (Peppered Moth).
Amphidasis prodromaria (Oak Beauty).
Odontoptera bidentata (Scalloped Hazel).
Phigalia pilosaria (Pale Brindled Beauty).
Boarmia repandata (Mottled Beauty).
Boarmia abietaria (Satin Carpet).
Boarmia rhomboidaria (Willow Beauty).
Gnophos obscurata (Annulet).
Hybernia progemmaria (Dotted Border).

Scheme of particulars :—

(1) State, if possible, the number of specimens of each variety (light or dark, &c.) of the above species that have been observed at rest, together with particulars as to the object upon which they were found, and also say whether they were conspicuous or well protected by their colour.

(2) State, if possible, whether the species is abundant, fairly common, or rare in the locality to which reference of the observation is made.

(3) If it is not possible to answer the foregoing questions, any other information concerning observations of a general character will be very acceptable.

All help received will be fully acknowledged on publication; and I would like here to express (as it has not yet been possible to publish anything upon the subject) my great indebtedness to those entomologists who have previously sent valuable information concerning the distribution, &c., of the various forms of *A. betularia* in their own particular localities in compliance with a former request.

The University, Manchester. H. S. LEIGH.

Protection from "White Ants" and other Pests.

IN a recent number of NATURE there was a note on the subject of ants in general and white ants in particular (they are not ants, but that does not matter, as they are "so called"), in which it is said that the Admiralty has decided in favour of "blue oil." Blue oil is the residue left in the distillation of mineral oils after the isolation of kerosine (called petroleum in England) and paraffin. I therefore venture to give you my experience in regard to the same and as to some other cognate matters.

Some twenty years ago I bought a cottage at Mittagong, about eighty miles from Sydney; it was furnished, and when I went there for a night I heard a continual rasping sound whilst in bed, and next morning, on examining the place, I found it was infested with white ants. They had eaten the pine lining in two rooms, as well as the uprights of a door.

I was then connected with a kerosine company, and immediately got a quantity of blue oil, which I had sprinkled all round the foundation of the house with a watering-can. The result is that the lining is in the same condition that it was twenty years ago. This is not an isolated instance, because during that time I have had much experience of "white ants," and have always found that they cannot work if they are cut off from connection with the ground, from which they get moisture, which is necessary for them, and they do not seem able to get through ground saturated with blue oil.

There is another matter to which I may refer in this letter. When I bought my present home, in 1882, I found it full of weeds and ants. I have got rid of both by extermination, and with the latter of aphis and almost entirely of scale insects. Of the former I have not seen one for the past fourteen or fifteen years. My first experience was with black aphis, by which the leaves of a nectarine tree were all curled up, whilst ants were continually running up and down the stem. I had read Sir John Lubbock's account of ants carrying the eggs of aphis to their nests, and I therefore shaved off the rough bark and chalked the stem for a foot or so, and the result was that the ants soon ceased to visit the tree, and we had a healthy tree and a fair crop of fruit. I may say that, so far as my observation goes, ants cannot climb up a chalked stem or post, as the chalk comes off with their feet and they fall down. I am not sure that this is the correct interpretation, as I have seen that if a broad chalk line is drawn round a meat-dish standing on a shelf the ants seldom get across it, and if they do it is only by some place being missed in chalking. They seem to leave a trace of formic acid behind them which guides the followers, and, combining with the calcium of the chalk, deprives them of their clue.

As to ants in general, I may say that after trying various ways to get rid of them I have come to an effectual method, that is, to find their nests and pour down each hole two ounces of a solution of cyanide of potassium. Two ounces per gallon is the strength I have used, but it might be weaker. The ants are not all killed by the first dose, for some are out foraging, and one cannot be certain of killing all the queens, but by giving them a dose once a week or a fortnight it is possible to get rid of them.

There is another matter I may mention. Some thirty-nine or forty years ago I observed an old shingle-roofed cottage at Maitland. It had two dormer windows, the sides of which had been painted white with white lead. The whole of the roof was rotten with fungoid growth except below the dormers, where the paint had been washed down by the rain, leaving a white streak, and there the shingles were nearly as good as they were when put on. It was therefore evident that white lead was inimical to fungoid vegetation.

When I came to my present home I had outside venetian blinds, and the "ladders" got quite rotten in three years, evidently by fungoid growths. In getting new ladders I steeped them in a solution of acetate of lead (6 ounces to the gallon), and they lasted for thirteen years, being by that time worn out by friction in moving them up and down. Acetate of lead is soon converted into white lead by atmospheric carbon dioxide. I have used the same process with a sheet surrounding a shower bath which in six months was black with "mould," and now it is in as good condition as it was ten years ago.

WILL. A. DIXON.

97 Pitt Street, Sydney, October 31.

January Meteors.

THE most noteworthy of the January meteor showers is that of the Quadrantids. Owing to the great northerly declination of the radiant, these meteors can be observed at any hour of the night, and being long-pathed they may, if fairly numerous, present quite a striking display. In 1911 the maximum will fall on the night of January 3, computed particulars of which and of other subsequent meteor showers are here summarised.

Epoch January 3, 11h. (G.M.T.), fourteenth order of magnitude. Principal maximum January 3, 12h. 30m.; secondary maximum January 3, 16h. 30m.

Epoch January 4, 13h. 30m., seventeenth order of magnitude. Principal maximum January 3, 12h. 40m.; secondary maximum January 3, 6h. 30m.

Epoch January 6, 22h., approximately sixth order of magnitude. Principal maximum January 5, 14h. 10m.; secondary maximum January 5, 2h. 45m.

Epoch January 6, 2h. 30m., fifteenth order of magnitude. Principal maximum January 7, 9h. 45m.; secondary maximum January 7, 7h.

Epoch January 11, 4h. 40m., eighteenth order of magnitude. Principal maximum January 12, 23h.; secondary maxima January 11, 4h. 40m., and January 12, 13h. 15m.

Epoch January 12, 19h., seventeenth order of magnitude. Principal maximum January 14, 9h. 20m.; secondary maximum January 14, 16h. 30m.

Epoch January 19, 17h., fifth order of magnitude. Principal maximum January 18, 7h. 30m.; secondary maximum January 19, 2h. 15m.

Epoch January 21, 8h. 30m., twelfth order of magnitude. Principal maximum January 22, 23h. 30m.; secondary maximum January 22, 18h. 30m.

The intensity of a meteoric epoch is inversely as its order of magnitude. Thus the heaviest maximum occurs on January 18, as it belongs to an epoch of the fifth order of magnitude, which is the highest of the month. Owing, however, to the times at which its maxima occur, and also to other circumstances, this epoch will not furnish so many meteors as the first two of the month, which have their principal maxima shortly after midnight on January 3.

Dublin. JOHN R. HENRY.

EXCAVATIONS IN CRETE.[1]

SWIMMING in the blue sea of the Gulf of Mirabello (well so named!), on the north coast of Crete, is a solitary isle, the name of which is beautiful in its Greek shape of Pseira, but by no means so lovely when translated into English, for ψεῖρα means "louse." The polite geographer Kiepert has in his map turned "Pseira" into "Psyra" (which is so much nicer), but Pseira, *Lausinsel*, is its name.

Photo.] [*R. B. Seager.*

FIG. 1.—Pseira, from Kavou i.

Seen from the west it reminds one of the Bass, but from the heights of the bridle-path leading over the cliffs from Kavousi to Tourloti, we see how low and insignificant it really is in comparison with the coast-hills; it looks little more than a long, low shoal. It is barren, and waterless, and no man lives there; only a few goats derive a precarious subsistence from the scrubby herbage which covers a portion of it; the rest is bare rock. Yet this unpromising place was the site, three thousand years ago, of a flourishing settlement of men, in which wealth existed and art was fostered.

Readers of NATURE will remember that some years ago Miss Boyd (the present Mrs. Hawes) excavated for the University of Pennsylvania an ancient Cretan town on the spot which bears the name of *Gournià*, on the mainland not far from Pseira; articles describing her work have appeared more than once in these columns. With her was working a young American archæologist, Mr. Richard B. Seager, who, after the close of the work at Gournià, excavated a settlement at Vasilikí, on the isthmus of Hierapetra, half-way between Gournià and Kavousi, which is opposite Pseira. The results of his work at Vasilikí were reviewed in NATURE of September 6, 1906. His next essay was the exploration of Pseira, where certain indications seemed to promise success in digging. Nor were these expectations disappointed. On the small tongue of land which forms the eastern side of the tiny cove which is the harbour of Pseira (a haven just large enough to hold a couple of caïques), were discovered the remains of an ancient town, with streets of houses descending steeply to the sea. It was a tiny place, though when it was made it was bigger than it seems now, for the land has sunk everywhere along this coast since the old Minoan times, and now the waves wash into the houses. All the ancient Cretan towns of the Bronze age seem to have been small, as was Gournià, judging by our standards, with narrow streets, some five feet broad at most, and cramped houses with tiny rooms.

But their small size was not the result of small ideas or lack of culture. In the ruined houses of these ancient towns have been found treasures of ancient art, of that most ancient art of Greece, the art of the Heroic age, which is older by a thousand years than the "Greek art" of the schools. And waterless, barren little Pseira has yielded objects of art finer than most of those found at Gournià, and hardly inferior to many of those discovered by Dr. Evans at Knossos (though, of course, in much less number). We may instance the relief fresco of the lady or

Photo.] [*H. K. Hall.*

FIG. 2.—The ancient town of Pseira, showing the excavations.

goddess published in plate v., and the vases in Fig. 9 and plate vii., of Mr. Seager's report on his excavations, which lies before us.

A cursory glance at these and the other illustrations of the report shows us that at Pseira the best traditions of Knossian art were followed, and it is evident

[1] "Excavations on the Island of Pseira, Crete." By Richard B. Seager. (University of Pennsylvania; the Museum; Anthropological Publications, vol. iii., No. 1.) Pp. 38+19 figures+9 plates. (Philadelphia: The University Museum, 1910.)

that the little island was really wealthier than Gournià, which at the time (about 1700–1400 B.C.) was probably the local provincial capital of the isthmus district. This wealth must have been due to seafaring trade, and probably to a great fishing industry, for agriculture there could be none on Pseira, even if in those days (as seems likely) there were water springs which now have dried up.

Then, about the end of the First Late Minoan Period (about 1500 B.C.), came a catastrophe. The town, which, like other settlements of the Cretan thalassocrats, even on the coast, was undefended by walls and open to attack, was taken, destroyed, and sacked by some unknown enemy. It never recovered, being only occupied for a short time during the Roman period.

To this disaster we owe, as Mr. Seager well points out, the preservation of so many objects of high interest. Gold, siver, and bronze were all looted and carried off; hence the comparative rarity of metal objects. But the fine pottery which is of so great interest to us now as evidence of the culture of its makers was unvalued by sea-robbers, and so, here, as elsewhere in ancient towns which have been destroyed by a catastrophe, we find this pottery and other remains of value to us exactly where it was left by the expelled or destroyed owners, or where the rage of the conqueror cast it forth. "On all sites the period of destruction is the one which leaves the richest harvest for the excavator. As long as a site is in continuous occupation the earlier deposits are only the refuse of breakage and objects which have ceased to be of service to their owners. They are thrown into rubbish-heaps and used as artificial fillings to make even floors over naturally uneven surfaces. Where, as at Pseira, the town was destroyed in the height of its prosperity, with no extensive later settlements to disturb its ruins, the finds are, of course, unusually rich" (p. 10).

I have no space for any critical discussion of technical points of archæology, but may say that Mr. Seager's description of his finds in this summary report is both able and interesting. The publication is well produced, its plates are admirable, and its line illustrations well and accurately drawn. It is a worthy addition to the series of anthropological publications of the Pennsylvania University Museum, of which it forms the first number in the third volume. Soon we hope to see a similar report on Mr. Seager's later and still more interesting discoveries at Mokhlos, another isle, east of Pseira, where tombs have yielded gold treasures like those of Troy, and as old. Mr. Seager is to be congratluated on his admirable contributions to the great work, important and useful alike to science and to art, which is being carried out by the excavators of ancient Crete. H. R. HALL.

THE LEAD GLAZE QUESTION.[1]

THE report referred to below is the outcome of the deliberations of a committee appointed by Lord Gladstone in May, 1908, to consider a question which has engaged the attention of the Home Office and Parliament for several years past, and has already been the subject of inquiry by several departmental committees. It is a matter of common knowledge that persons engaged in the making of earthenware and china are subjected to considerable risk to health from two main cases—dust and lead. The dust arises from the finely-divided silicious matter, mainly ground flint, employed in various stages and processes of ceramic manufacture; this when breathed gives rise to distressing bronchial and lung troubles, and in an aggravated form leads to the malady known as "potter's rot."

[1] Report of the Department Committee appointed to inquire into the Dangers attendant on the use of Lead and the Danger or Injury to Health arising from Dust and other Causes in the Manufacture of Earthenware and China and in the Processes incidental thereto, including the Making of Lithographic Transfers. Presented to both Houses of Parliament by Command of His Majesty. Vol. i. Report. Pp. vii+150. (London: H.M.S.O., 1910.) Price 1s. 5d.

The danger arising from dust may be largely obviated by the use of mechanical and other appliances whereby the operative is prevented from inhaling the dust-laden atmosphere. By the more general use of exhaust-fans or other suitable ventilating machinery, and by the employment of respirators, cases of "potter's rot" are less frequent now than formerly. At the same time much remains to be done by a more stringent application of these remedial measures. It was only in 1894 that the Home Office issued the first code of special rules dealing with dusty processes. The evil is patent and notorious; it is, however, not very satisfactory to be told that we must wait for the statistics of 1920–2 before we can estimate the real value of these special rules. If public opinion moved as fast on the dust problem as it has on the lead question, we should not have to wait ten or twelve years before this crying evil was absolutely stamped out, and "potter's rot" become as much a thing of the past as "phossy jaw."

It is, however, mainly to the dangers attendant on the use of lead in pottery manufacture that public sentiment has been roused, and it has been largely in deference to this feeling that the several departmental committees above alluded to have been appointed. It is only by "pegging away" in this manner that such amelioration as has been secured has been reached.

The pottery industry in this country is mainly centred in North Staffordshire. Of the 63,000 workers in the 550 factories scattered throughout the United Kingdom, 48,000 are employed in the 329 "potbanks" in the district known as the "Potteries." Owing to special circumstances, arising largely from local conditions of employment, no systematic attempts to grapple with the evil of lead poisoning have been made by the manufacturers as a body. Individual firms, with intelligent management, have succeeded in minimising the mischief, but the laxity of other firms has at times more than neutralised the benefits which have been secured by the more general adoption of the precautionary measure which common-sense seemed to indicate and experience has shown to be adequate. The manufacturers as a body have, in fact, been content to wait until outside pressure has forced them into action, mainly by rules and regulations issued by the Home Office, and based on the suggestions or recommendations of departmental committees appointed *ad hoc*.

The committee which has now reported has gone over much of the ground already traversed by its predecessors, or which occupied the attention of those engaged in the prolonged arbitration under Lord James, leading up to the special rules of December, 1903. But it cannot be said that any real progress has been made. Although it has been established that a large amount of earthenware can be made without the use of lead in any form, and even in the cases where lead must be used, it has been proved that the lead may be so combined that it is practically innocuous, the manufacturers as a body have hitherto resisted any attempt to prescribe a schedule of articles which should be made with leadless glaze, or to bind themselves to use glazes in which the lead is in an innocuous form. They, in fact, demand unrestricted liberty to use any materials they think necessary for their purposes. The loud cry of "foreign competition" is sufficient to drown the still, small voice of pity raised on behalf of the workers.

Now it is absolutely certain that under such conditions lead-poisoning in pottery manufacture will continue to occur. The leading manufacturers, through their counsel, in the course of the arbitration proceedings before Lord James of Hereford in 1903, promised the extirpation of lead-poisoning under the rules then proposed, but that promise has not been kept. On the contrary things are as bad as ever. That more might be done under the rules as they stand would seem to follow from the statistical information furnished by the committee. They examined into the record of the 550 potteries which have been placed under these special rules during the period 1904 to 1908, and they find that during these five years:—

5 potteries have been responsible for			75 cases
17	,,	,,	,,	119 ,,
151	,,	,,	,,	323 ,,
In all 173	,,	,,	,,	517 ,,

leaving 377 potteries out of the 550 in which no cases have occurred at all. In other words, 32 per cent. have an average of three cases every five years, while 68 per cent. are entirely free from the disease. In the 173 potteries in which the disease has occurred there are 4,800 workers as against some 2,000 in the other potteries. The conclusion would seem to be obvious. It is in certain relatively large works that the cases of lead-poisoning are most frequent, and this can only be due to bad management, imperfect supervision, or inadequate protective appliances.

During the period 1901–9, 865 cases of lead-poisoning in pottery workers were reported. Of these 788 arose from glaze processes, whereas only 51 were due to decorative processes. Lead glaze is therefore the main cause of the evil.

It cannot be said that the conclusions of the committee now reporting have tended in the slightest degree towards a solution of this grave evil. All the conditions to which lead-poisoning in ceramic manufacture is due are perfectly well known, but the committee was apparently unable or unwilling to make any definite suggestions as to remedies. The committee pleads that it was in a difficult position. The members of the committee representing the manufacturers were entirely opposed to any restriction in the use of raw lead; the representatives of the workers, seeing the comparatively harmless character of low-solubility glazes, would be glad to see them generally introduced, "but have to consider the grave risk of loss of employment which any dislocation of the industry due to their introduction might entail." *Might,* not would. Taking the question of glazes as a whole, two facts, says the committee, are beyond dispute:—

"In the first place, the danger to the workers of handling raw lead is very real; in the second, it is evident that however unsuitable leadless and low solubility glazes may be for certain classes of ware, there is a considerable quantity made for which they are quite satisfactory."

But the members of the committee are unable to make up their minds what classes of ware are represented by this "considerable quantity," although the facts were before them. They think, however,

"that every inducement and encouragement should be given to the manufacturers both to persevere with their experiments in search of satisfactory and low-solubility glazes, and to introduce them whenever possible."

Also efforts should be made to arouse the interest of purchasers in the question. The members think "it was established that pottery made with leadless and low-solubility glazes can be obtained of excellent quality," and they "consider that the desirability of insisting on being supplied with such ware should be brought home to the public at large." Lastly, they are of opinion that—

"the observance of the special rules has been far from satisfactory. In the past many of the manufacturers do not appear to have regarded it as incumbent on them personally to insist upon it; they have left the initiative to the factory inspectors, and in future they should be made to realise that they are themselves responsible."

The committee obviously had not the courage of its convictions. It is difficult to imagine any more feeble or inconclusive "conclusions." No constructive action seemed to be possible to it; its only policy was that of *laissez-faire*. The net upshot of the inquiry is that the whole position is not one whit ameliorated; the operatives apparently are still to remain the victims of lax surveillance or of indifference, and of official non-interference.

The matter, however, cannot be allowed to rest in this position. If the manufacturers' claim for unrestricted liberty to use such dangerous materials as they please is to be allowed, they must be made to feel the responsibility they therby incur by far more stringent measures than have hitherto been brought to bear upon them.

THE NEW ENCYCLOPÆDIA OF SPORT.[1]

WHETHER by design or by accident, the new edition of this work has appeared at an opportune time, since the success of the Vienna Exhibition has attracted an even more than ordinary amount of attention to sports and pastimes of all sorts during the year now rapidly coming to a close. Those who

Photo.] [*W. S. Berridge.*

Himalayan Tahr. From "The Encyclopædia of Sport."

possess the first volume of the original edition will find, on comparing it with its successor, a great change in regard to much of the subject-matter, aviation having been practically created since the date of the appearance of the first edition, while during the same period motors have come to the front as a means of communication, and everything in connection

[1] "The Encyclopædia of Sport and Games." Edited by the Earl of Suffolk and Berkshire. New and enlarged edition. Vol. i., A to Cricket. Pp. viii+496. (London: W. Heinemann, 1910.) Price, 10*s.* 6*d.* net at home; 12*s.* 6*d.* net abroad.

with automobiles has been revolutionised. So far as I am capable of judging, these articles, as well as those devoted to archery, athletics, cricket, &c., are thoroughly up to date, and, like the rest of the volume, admirably illustrated.

On turning, however, to the articles on big game and big game shooting, I notice that there is a considerable amount of repetition and overlapping, while, worse still, one and the same species of animal is in several instances mentioned in different places under different names. In the case of the reindeer or caribou, for example, the scientific name of the species is given on p. 264 as *Rangifer tarandus*, on p. 399 as *C.* (=*Cervus*) *tarandus*, and on p. 401 as *Tarandus rangifer*. Take again the case of the Indian gazelle (*Gazella bennetti*), which is figured, quite unnecessarily, in three different places. The first figure, p. 75, bears the legend "Ravine Deer"—a common sportsman's name—while it is alluded to in the text as the "Chinkara"; on p. 256 the illustration is lettered "Indian Gazelle," while on p. 412 the same figure reappears under the designation "Chickara." Again, the West African dwarf buffalo is designated *Bos caffer nanus* on p. 248, and *Bos pumilus* on p. 319.

These eccentricities in nomenclature are, however, by no means all the defects in the articles under consideration. The chita, or hunting leopard, for example, in addition to being styled *Cynaelurus jubatus* on p. 408, and *Felis jubata* two pages later, is stated on the former to be nearly related to the leopard; and on p. 410, the Indian spotted deer, or chital, is asserted to be a near ally of the fallow deer, despite the fact that the one wears its spotted livery all the year round and the other only in summer. Worse than all, we find on p. 250 a photograph described as that of the western tur (*Capra caucasica*), whereas it is really of the same individual as that depicted on p. 252, under its proper title of tahr (*Hemitragus jemlaicus*).

An error of another kind appears in the first article under the heading bison, which is devoted solely to the American representative of the group, whereas it should have commenced with the European species, which is the bison *par excellence*, the American animal having only a kind of courtesy right to the title.

These and others errors are due, in the first place, to what I regard as the pernicious principle of putting men of different opinions, and in many cases of very different degrees of knowledge, to write on the same subject or branches thereof, and in the second place to the lack of a competent editor to revise and correlate the zoological articles, and thus prevent useless and irritating repetition.

While fully appreciating the value of the work as a whole—which is really a wonderful enterprise—the above and other errors in the big game portion are much to be deplored, more especially as the articles are intended for the use of those who are not professed naturalists.

R. L.

WESTERN CHINA.[1]

MR. ARCHIBALD LITTLE'S work, the result of fifty years spent in western China, forms a valuable contribution to our knowledge of that vast region. The volume before us is invested with special interest, as it is the remnant of the labour to which he devoted the greater part of his life. He was at heart an explorer, although in business as a merchant in Chung-keng, much of his time was spent in difficult and dangerous expeditions, which he carried out so successfully as to establish his fame, not only as an intrepid traveller, but as an authority on the western provinces of the empire. He was an exception to the majority of the foreign merchants one meets in China in his having acquired a

[1] "Gleanings from Fifty Years in China." By the late A. Little. Revised by Mrs. A. Little. Pp. xvii+330. (London: Sampson Low, Marston and Co., Ltd., 1910.) Price 7s. 6d. net.

working knowledge of the language, which proved of service to him in his travels and intercourse with the natives, and in obtaining trustworthy information.

The present volume, unlike its predecessors, is made up of a series of desultory notes or essays written at intervals during his fifty years in Chung-keng, the majority having already appeared in some published form, while the remainder are printed for the first time. Taken together, they form an interesting addition to the author's well-known work, and are published as they were written, no attempt being made to edit or rearrange the material. It is best so, as they are characteristic of the author, who won his way to the hearts of the alien folks among whom he lived and wandered in security for so many years, a people who would fain see the last of the average foreigner, whose aggressive commercialism they do not love.

In his discussion of foreign trade with China the author traverses familiar ground, but he affords some insight into Chinese diplomatic delays in his account of the years spent in fruitless endeavour before Chung-keng was thrown open as a treaty port. Mr. Little was the first to take a steamer through the gorges of the Upper Yangtse, a feat so daring and hazardous as to prove what had been foreseen, that the route was impossible for regular steam traffic.

FIG. 2.—A quiet reach on the Upper Yangtse. From "Gleanings from Fifty Years in China."

In his historical notes on the provinces from Marco Polo's time, who was the first to describe the region, he states that an interval of some 600 years elapsed before Abbé Huc gave some further account of the country in 1844. He overlooks the claims of Fradelli, Regis, and Bonjour, who, early in the seventeenth century, surveyed and described the western provinces of China, their products, and people.

We can do little more than name some of the other subjects dealt with in the volume—the possible partition of China, China's Christian missions, an essay in which the views expressed may not meet with the approval of those engaged in the work, although he pays a just tribute to the workers as "the promoters of all good in the advance made by China in the past fifty years."

The concluding chapters on the Chinese drama, with examples of native plays, and on Confucianism are new, and sustain the scholarly reputation of the author. A series of excellent photographs add to the attraction of the volume. J. T.

THE CALORIMETRY OF MAN.[1]

A GREAT deal has been said previously as to the general excellence of the methods and apparatus developed in connection with the "respiratory calorimeter" now in use in the Nutrition Laboratory in Boston. That they are original and are carried to a unique degree of perfection, that they have been utilised in the solution of very interesting problems. All this is well known, and will be found frequently dealt with by the authors of the publication referred to below. Gratitude has been freely expressed on these points.

In this recent publication the authors, experienced investigators advantageously equipped for the purpose, have set themselves the task of laying a base line for further calorimetric research. They will receive the thanks of every interested technical observer for the splendid series of data which they have compiled, but they have overhauled them in a manner open to some criticism.

To develop this statement let us take one set of their facts, namely, that the oxygen consumption and heat production of the human being vary during periods of sleep within wide limits when assessed per man, or per kilo of man, or per square metre of the surface of man. Of these three forms of assessment, the last is the most interesting since the loss of heat, and therefore the oxygen consumption and heat production by which it is compensated, is largely conditioned by extent of surface. Now it is of some importance that no surface measurements have been made and that the estimations of surface are really derived from the measurements of weight. The authors refer to this point with some expression of regret, and a promise of contributory data, again of an indirect kind, in future. It would, however, have been of far greater interest had they dealt soundly with their data of height and weight in such a way as to show with unmistakable clearness that no probable corrections in their surface estimations will account for the differences in heat loss observed. A clear statement that they had found variations not accounted for, *and never likely to be accounted for*, by variations in surface would have been of substantial value.

That this end might have been met by an adequate comparison of the measured heights and weights of their "tall lean men, tall men, short fat men, short men," with average anthropometric data, there can be no doubt whatever. Thus let us take the particular instance of the individual giving the minimum heat loss per man, or per kilo, or per square metre of the surface of man, as compared with the seventeen other individuals whose fortunes can be followed through most of the tabulated statements. His height may best be described as the cube root of his

[1] "The Metabolism and Energy Transformations of Healthy Man during Rest." By F. G. Benedict and T. M. Carpenter. Pp. viii+255. (Carnegie Institution of Washington, 1910.)

weight multiplied by 4·5. Armed with a convenient table of cube roots and plenteously available data, it will be found that this man is a departure from the average, but a departure in the opposite direction to that which would promise the concealment of much weight under a partially spherical and disproportionally small surface. In this country at least the average height of the youth from eight years of age to eighteen is $4·3\sqrt[3]{W}$, whereas the stouter child and adult above and below these ages is liable to possess smaller heights, such as 4·2 to $3·7\sqrt[3]{W}$.

So far is this man's rate of heat-loss per estimated square metre of surface below the average, and so unlikely is it that direct measurements of his surface will lead to any compensatory change in the statements such as would bring it near to the average, that it might have been of value to direct special attention to his indisputable peculiarity. Had this been done, another peculiarity of his might perhaps have been brought to mind and have been found of interest, namely, that he is a veteran *habitué* of the calorimeter. It may be suggested, indeed, that this is the important fact inasmuch as it enabled him to sleep amidst these peculiar surroundings and modified atmosphere with unusual unconcern. That unconcern is truly a factor of some importance may perhaps be gathered from a consideration of the unexplained greater evaporation of water from the surfaces of the few women bold enough to enter the calorimeter. It might be suggested that there is no mystery in the fact that these ladies perspired unduly.

It is almost certain that this particular case might legitimately be used to illustrate the statement that sleep, like scientific literature, is sometimes profound although often not so. It is indeed a well-known fact that the excitability of the nervous system during sleep is a very variable value, and it is extremely probable that its variations are attended with changes in the "tone" of the skeletal musculature, and therefore with modifications in the quantity of concurrent metabolism. Once take this point of view, which is apparently not dealt with by the authors, who describe all alike as being in profound sleep, and it will, on sound grounds, be found that there is not one of these recorded cases that does not require some consideration in these terms. Thus it will be found that every individual with a metabolism during sleep that is below the average value by more than 5 per cent., awakes to a metabolism increased by from 26 to 63 per cent., whereas every individual with a metabolism in sleep greater than the average by more than 5 per cent. awakes to a smaller increase varying from 10 to 22 per cent. It is necessary to suggest that the one set awake to a relatively much greater increase of metabolism because they awake from a more profound state of slumber. Nor is the suggestion the less necessary when it is discovered that although several not infrequent visitors to the calorimeter are found on either side of the average, yet the initials of the best-known *habitués* are found in the heavy slumber class and those of certain restless probationers in the list of light sleepers.

J. S. MACDONALD.

NOTES.

IN a four-column article which appeared in the *Times* of December 22, the outbreak of plague in East Anglia, and particularly the rat-infection in the locality, is dealt with ably and exhaustively. The writer of the article points out that no adequate measures have yet been taken to deal with the situation, and urges that it is one of national importance and for direct Government intervention. It is suggested that a sum of 10,000*l*. at the very least is required to prosecute the necessary inquiries and investigations, and that there is immediate necessity for expert inquiry under Government control and at Government expense. Compared with the issues involved, the expenditure of such a sum, or even one many times larger, need not be considered, and the course of action recommended will commend itself to those who have a real knowledge of plague, and it is to be hoped that the authorities will speedily take in hand an organised scientific inquiry into the outbreak of plague in England and the remedy for its control. Similar views in outline were expressed in the article on "Plague" which appeared in NATURE of the same date (December 22, p. 237).

THE appalling loss of life associated with the terrible colliery disaster at the Yard Mine of the Hulton Colliery Co. at Bolton, Lancashire, has again emphasised the desirability of perfecting, so far as is practicable, the warning of approaching danger. The explosion, which occurred shortly before 8 a.m. on Wednesday, December 21, resulted in the loss of about 350 lives. The *Times* of December 22 says the disaster followed immediately upon a colliery warning, which appeared on Monday in newspapers circulating in various mining districts, and the warning was said to be in continuation of one which had been circulated a week earlier. Such warnings are not, however, issued by the Meteorological Office. With the advance made in recent years in our knowledge of weather changes, it seems desirable to determine the atmospheric conditions under which explosions generally occur, and, if possible, to place the warnings of approaching danger on a scientific basis and to make some public authority responsible for the issue of such warnings. The weather chart for 7 a.m. December 21 issued by the Meteorological Office is of quite a common type, and is representative of many such occurrences in the course of an English winter. A region of low barometer was situated to the south of Iceland, and a region of high barometer was situated over Germany. The barometer at this time was fairly steady at about 29·95 inches over Lancashire. Examining the atmospheric conditions under which fifteen of the greatest colliery disasters of recent years occurred, between the years 1880 and 1910, there is a preponderance of explosions with a high barometer, and about the time that the central area of an anticyclone is situated in the neighbourhood. There are, however, marked exceptions to this, and the disaster near Wigan on August 18, 1909, occurred when an area of low barometer readings was centred close by. Irrespective of the absolute height of the barometer, the instances examined seem to occur about equally with a rising and a falling barometer.

A BILL to make Paris official time coincide with Greenwich time was presented to the French Senate on December 21. The Bill was passed by the Chamber of Deputies several years ago, and has been approved by the senate committee and by the Cabinet, so that in all probability it will become law. Paris time is 9m. 21s. ahead of Greenwich time; and upon the day prescribed by the law, the clocks indicating official time in France will be put back by that amount. By the adoption of the change, France will be brought into the international system of Standard Time reckoning which is now followed in most civilised countries. On this system, the hour of each successive fifteen degrees of longitude, reckoning from the Greenwich meridian, is used for the Standard Time; hence the difference in time in passing from one zone to another is always an exact number of hours.

IT was announced a short time ago that a new zoological garden in course of construction by Mr. Carl Hagenbeck in the grounds of the Villa Borghese, Rome,

would probably be opened on January 1. The grounds, which comprise twenty-eight acres, lie outside the old walls to the northward of the city, and it is stated that more than 40,000*l.* has been already spent on them, while the animals, some 1400 in number, represent another 10,000*l.* As at Stellingen, cages have been to a great extent dispensed with, deep ditches and scarped cliffs serving to confine the animals, which thus appear to be at liberty.

THE Zoological Society of London has elected the following corresponding members:—Mr. Roosevelt, ex-President of the United States; Mr. B. Basu, Calcutta; Mr. J. M. Doctor, Bombay; Dr. R. Dohrn, Naples; Prof. Ludwig von Graff, Graz University; Mr. W. H. Osgood, Washington, U.S.A.; Mr. H. Pam, Caracas; and Mr. R. B. Woosnam, Nairobi. Prof. E. Lönnberg, Stockholm, and Mr. S. H. Scudder, Cambridge, Mass., U.S.A., have been elected foreign members of the society.

WE learn from the *Chemist and Druggist* that the branch laboratories of the Pasteur Institute of Paris, at Garches, near St. Cloud, which are specially used for the preparation of anti-diphtheric and other serums, took fire a few days ago, and damage to the extent of 4000*l.* was done.

THE International Horticultural Exhibition which is to be held in the Chelsea Hospital grounds at the end of May, 1912, promises to have considerable scientific interest. There has only been one show of this nature in Great Britain, namely, that of 1866, which was held at South Kensington. Although the 1866 Exhibition was, in the end, a magnificent success, it very nearly proved disastrous to those responsible for the finances. The ultimate success was obtained by the committee prolonging the period the exhibition was open for public inspection, and the balance which resulted from this policy was devoted partly to the purchase of the Lindley library, at present housed in the Royal Horticultural Society's Hall at Westminster, and partly to making a donation to the funds of the Gardeners' Royal Benevolent Institution. In connection with the exhibition there was held an International Congress, and a valuable report of the proceedings was printed which is still a lasting record of the work and interest that were freely given by the horticulturists of that day. In 1912 a similar congress will take place, and subjects of international importance to the horticultural industry will be discussed in the presence of representatives from most of the European countries, America, and our own colonies. It is expected that the congress will consider the question of the regulation of insect pests and fungus diseases, and the effects of the prohibition of the importation of certain plants to certain countries, for instance, by the Phylloxera laws in the wine-producing countries. Certain other questions suggest themselves as ripe for discussion; for example, the improvements which have been effected in plants in recent years, the different methods by which those improvements have been obtained, and horticultural education, with special reference to the methods of training young horticulturists in this country and on the Continent of Europe and in America. A committee largely composed of scientific men has been appointed specially to promote the congress and a scientific section of the exhibition. The horticultural show itself is expected to be the largest ever held in this or any other country. There are already 431 competitive classes, and many of these are of scientific interest, but we must reserve any further remarks for a future occasion. Copies of the schedule can be obtained from Mr. Edward White, 7 Victoria Street, Westminster.

MR. J. GRAY contributes to the December number of *Knowledge* an article on the measurement of perseveration and its value as an index of mental character. In point of fact, Mr. Gray does not measure perseveration, but the speed at which rapid flashes of colour just succeed in extinguishing flicker in various subjects. He assumes that the individual differences with which he meets are due to differences in the persistence of colour sensations, and that "this persistence . . . is identical, or very closely related, to a quality of mind which the psychologists call Perseveration." The experimental facts which the paper contains are two, viz. that flicker disappears more readily in women than in men, and perhaps more readily in dark-haired than in light-haired persons. The nature of these differences awaits careful psychological investigation.

IN the *Revue générale des Sciences* for October 15 and 30 Prof. Marinesco, of the University of Bucharest, has given an interesting summary of recent investigations upon the anatomical localisation of the human cerebral cortex, and more especially of the distinctive cytological characters of each of the multitude of areas into which the pallium of the brain can now be subdivided. His descriptions are elucidated by a series of twenty-seven drawings exhibiting a wealth of intricate detail. The articles are essentially a digest of the work accomplished by others, and especially of the classical researches of Oskar and Cecilie Vogt and Karl Brodmann. Although Prof. Marinesco's citations of the results and the opinions expressed by other anatomists are not always exact, on the whole his summary will be useful to those who are unable to find time to read the voluminous literature upon which it is based.

THE Journal of the Quekett Microscopical Club for November (ser. 2, vol. xi., No. 67) contains a critical paper on the classification of the Bdelloid Rotifera which should be of great value to students of this difficult group. The same number contains an interesting echo of the British Association's visit to South Africa in 1905 in the description, by Prof. G. S. West, of a remarkable new species of Volvox collected by Mr. Rousselet in Rhodesia. The adult colonies are about 1 mm. in diameter, and may contain more than 50,000 cells. Another paper also deals with the microscopic fresh-water fauna of Africa, being a contribution to the list of Hydrachnidæ found in the East African lakes, by Mr. Charles W. Soar. The material upon which this paper is based was collected during the third Tanganyika expedition conducted by Dr. W. A. Cunnington.

IN the *Centralblatt für Mineralogie, Geologie u. Paläontologie* for 1906, p. 450, Dr. O. Abel founded a new genus and species of bird (*Alabamornis gigantea*) on two bones from the Alabama Eocene, regarded by Dr. Lucas as the pelvis of a Zeuglodon, these bones being described as coracoids of the bird. Dr. Lucas wishes to state that there is no doubt whatever as to the correctness of his original determination, and that the bones in question have been mounted in their proper position in the Zeuglodon skeleton which is now exhibited in the U.S. National Museum. "Alabamornis" must accordingly be deleted from the list of fossil bird genera.

DR. F. A. LUCAS writes to say that the "Open Letter" of the Campfire Club on the fur-seals of the Pribilows, which was referred to in NATURE some months ago, contains several misstatements, more especially the assertion attributed to the authorities that unless 95 per cent. of the males were annually killed the herd could not increase. In the Recommendations of the Advisory Board, of which

Mr. Lucas has enclosed a copy, the statement is "that not more than 95 per cent. of the three-year-old male seals be killed in any one year," which is, of course, a very different matter. Mr. Lucas adds that all male fur-seals over a certain size are not killed, but left to grow up, and that under the rules in force for the last five years the number of adult males has steadily increased, while the females have as steadily decreased, and will doubtless continue to do so if pelagic sealing be not stopped.

In a paper on animals in Glen Garry Forest, published in vol. vi., part iii., of the Transactions of the Edinburgh Field Naturalists' and Microscopical Society, Mr. Symington Grieve states that whereas half a century ago the sea-eagle was far more numerous in Scotland than the golden eagle, at the present time precisely the opposite of this is the case. The golden eagle, owing to the protection afforded to it by landowners, is increasing in numbers throughout the Highlands in suitable districts. On the other hand the sea-eagle, which formerly abounded on the cliffs of the west coast, has nearly disappeared, and in the author's opinion, in default of more efficient protection than it at present receives, will cease to breed in Britain within a few years. Mr. Grieve is also of opinion that the wild cat is on the increase in Scotland, owing to the instructions issued by proprietors and factors for its preservation.

In an article on the spawn and larva of the salamander *Amblystoma jeffersonianum*, published in the *American Naturalist* for December, Prof. W. H. Piersol directs attention to the low vitality of many of the eggs. Although no accurate census has been taken, it is estimated that under natural conditions three-fourths of the eggs do not live to commence gastrulation, and the same proportion of loss occurs in spawn kept in the laboratory. The egg does not die as a whole, but while some cells perish at an early period, others develop to a certain stage, only to die later. These dead eggs imbibe water and become larger than the rest, and in the natural condition become infested with a fungus. Since, however, this fungus does not make its appearance in spawn reared in the laboratory, it is manifest that the mortality is due to some other cause. On the other hand the spawn of the allied *A. punctatum*, both in the natural condition and in the laboratory, suffers practically no loss.

The Live Stock Journal Almanac for 1911 contains the usual amount of valuable information regarding horses and pedigree stock of all kinds for 1910, together with a number of articles on subjects of current interest by various specialists. Sir Walter Gilbey, for instance, discusses the effect of the rapid increase of motor vehicles on the prices of horses, and finds that although fewer horses are required in this country than was the case ten years ago, yet prices in all classes are fully up to their old level. This affords evidence that the supply has fallen *pari passu* with the demand, and this, from a military point of view, is a serious matter. On the other hand, the demand for shire horses is fully maintained. In another article Lord William Cecil directs attention to the value of our mountain and moorland breeds of ponies, on account of their stamina and hardiness, and advocates that Government should take into consideration the advisability of breeding a serviceable class of horse from pony mares. In an article on the connection between the various breeds of British cattle and the nature of the soil on which they are reared, Mr. P. McConnell revives the theory that the red colour of Herefords is connected with the red rocks of their native county. He forgets, however, to add that the Sussex breed is also red. Apparently he also believes that white park cattle are an aboriginally wild stock.

Dr. Guido Sala (*Mem. R. Ist. Lombardo Sc. e Lettere, Classe Sc.*, xxi., fasc. iv.) has published some interesting observations on the cells of the ciliary ganglion. In the human fœtus of six or seven months the cells are comparatively simple; they have few superficial prolongations (each ending in a bulbous enlargement), and a pericellular network is seldom present. At the time of birth the cells and their processes are larger, and six or seven months later loop-like outgrowths of the cell begin to appear, and later become more numerous, larger, and more complex. In adults there is a complex pericellular network of fine deeply staining fibrils, which completely envelops the cell, and there is often a spiral fibril round the axone. In old persons the cells exhibit modifications and assume almost the aspect of embryonic elements, and the protoplasmic processes of the cell are, for the most part, short and thick. In the same memoirs (fasc. iii.) Prof. Livini gives some notes on the development of the trachea in the chick. In embryos of about ninety-four hours' incubation the lower end of the trachea and the origins of the bronchi become narrowed and then occluded, but the lumen is restored before the one hundred and eighteenth hour of incubation. A little later the greater part of the trachea becomes similarly narrowed and temporarily closed.

Among thirty-one forms of lichen collected by Ir. M. Shegolef in the Jugjur chain (Stanovoi), *Umbilicaria caroliniana* and *Usnea cavernosa* are of special interest, as the former has been previously reported only from America and the latter only from America and India (Bulletin of the Imperial Academy of Sciences of St. Petersburg, No. 7, 1910). *U. cavernosa* seems to be widely distributed in eastern Siberia, for it is abundantly represented in Shegolef's collection.

Among ostracoda collected by D. Pedashenko in Issyk-kul is *Herpetocyprella mongolica*, of a new genus which resembles Candona and Eucandona in the absence of swimming bristles to the second pair of antennæ, but is very different in many other respects (*Travaux de la Soc. Imp. des Naturalistes de St. Pétersbourg*, vol. xxix., fasc. 2, part i.). Other new species are *Cypricercus mongolicus* and *Cytheridea pedaschenkoi*.

At the annual meeting of the Lancashire and Cheshire Entomological Society, held in Liverpool on December 19, Mr. R. Newstead, of the Liverpool School of Tropical Medicine, delivered his vice-presidential address on "Some Morphological Characters of the Genus Glossina." He stated that he has made a careful examination of the armature of the males of all the hitherto described species of the genus Glossina, and it has not only revealed some very striking morphological characters, but has led to the discovery of three hitherto undescribed species:—*Glossina submorsitans*, Newst.; *G. brevipalpis*, Newst.; and *G. fuscipes*, Newst.; and the re-establishment of Bigot's *G. grossa*. The scheme of classification adopted is based entirely upon the taxonomic characters of the male armature, which are the true and almost only natural anatomical elements that can at present be found in these insects. Mr. Newstead has found that the species fall into three striking and distinct groups, each being separated by very trenchant characters. The groups are:—(1) The *fusca* group, including the four largest species of the genus: *G. fusca*, Walker; *G. grossa*, Bigot, which have a western distribution; *G. longipennis*, Corti;

and *G. brevipalpis*, Newstead. (2) The *palpalis* group, to which belong the species: *G. palpalis*, Rob.-Desv.; *G. tachinoides*, Westwood; *G. fuscipes*, Newstead; and *G. pallicera*, Bigot. (3) The *morsitans* group, comprising *G. morsitans*, Westwood; *G. submorsitans*, Newstead; and *G. longipalpis*, Wiedemann. In these three groups forms occur which are so widely different as to lead one to assume, without taking the other external features into consideration, that they represent three distinct genera. Certain it is that these insects illustrate one fundamental principle of evolution, namely, that they have attained great development of one set of morphological characters, and have retained others apparently of an ancestral type.

THE difficult question whether acquired characters can be inherited is discussed by Dr. Hugo Fischer in the issue of *Naturwissenschaftliche Wochenschrift* for November 20 and the following number. Examples among unicellular organisms are accepted in the cases of the sporeless races of fission fungi and the colourless variety of *Micrococcus prodigiosus*; also the chromatic modifications of Oscillaria and the physiological varieties of numerous Uredineæ and Ustilagineæ are cited as good instances. Amongst animals, the author notes the experiments of E. Fischer and others, who produced more than transitory changes of colour in butterflies by subjecting the pupæ to abnormally low temperatures, and Kammerer's results with salamanders. In the case of flowering plants, the author holds that the Alpine forms of larch and pine and Wettstein's seasonal forms of Euphrasia and Gentiana are not definite examples, but admits the races of maize produced by Blaringhem and the modified type of Sempervivum raised by Klebs. The essential factor appears to be a disturbance of the metabolism.

A COPY of the annual report for 1909, dealing with technological museums, has been published by the Technical Education Branch of the Department of Public Instruction of New South Wales. The report is an excellent record of steady progress. A considerable number of exhibits were added to the collections during the year. The display of polished marbles and building stones of New South Wales in the museum at Sydney has been largely added to, and the whole now makes a fine exhibit. For comparative purposes, slabs of the principal foreign marbles have been displayed upon the walls in an adjoining court. To increase the available knowledge of the constructive value of the building stones, a special collection was obtained from various parts of the State, and prepared for testing at a 100-ton machine. Fire and water tests upon specially prepared cubes were next undertaken upon the sandstones, trachytes, marbles, and granites. The location of deposits of building and ornamental stones occurring in the area included in the Federal capital site was determined, and specimens of these materials procured. The data obtained, together with a specially constructed map, were published as an appendix to the second edition of the museum's work on the "Building and Ornamental Stones of New South Wales." The public-school teachers of the district take advantage of the facilities offered by the museum in the furtherance of nature studies; 1567 specimens were identified for teachers during the year, not including those brought to the museum by teachers and pupils; 865 specimens were supplied from duplicate collections to assist the teachers in the formation of school museums. Specimens were identified and classified for a large number of schools throughout New South Wales.

MRS. M. OGILVIE-GORDON continues her studies of the Triassic masses above the Grödental, in Tyrol, in the *Verhandlungen der k.k. geol. Reichsanstalt* for 1910 (pp. 219 and 290). In 1908 she visited the Boégipfel region with Prof. Rothpletz and Herr von Klebelsberg, and verified the overthrust of Raibl beds on Dachstein dolomite. Neocomian strata were found resting on Jurassic north and south of the Eisseespitze; these lie below the overthrust. The sections of the Boé and Jägerschart masses show remarkable discordances due to thrusting, even among the Jurassic strata, and the Upper Triassic beds climb up boldly on the crests. Similar overthrusting has been studied by the author in the Sella and Langkofel area (Trans. Edinburgh Geological Society, 1909–10). In the second paper in the *Verhandlungen* the discovery of fossiliferous Cassian beds is recorded from under the Burgstall, a part of the Schlern mass where a dolomitic and contemporary facies was believed to exist. The dolomite on this level farther west is attributed by the author to the occurrence of an overthrust, whereby the Cassian horizon is brought above a wedge of the Schlern dolomite, which properly should overlie it, as it is seen to do on the Gamsteig and the Burgstall.

THE *Geologische Rundschau* (Leipzig: Engelmann), which was recently started as a journal of general geology, continues on the broad lines laid down by its originating society. Prof. Steinmann, for instance, describes and illustrates in parts ii. and iii. the structure of the Cordillera of South America. M. Semper summarises seventy papers on the "Klimaproblem der Vorzeit," a labour that will surely rejoice his fellow-members. P. Wagner furnishes a list of 127 German works and papers bearing on geological teaching in schools and on the treatment of geology so as to promote interest and observation. His introductory essay of sixteen pages reminds us that the main object of the *Rundschau* is to bring the geological features of Germany and Austria to the front in public education. It is clear from his review that there is already a healthy movement to draw even scholastic mineralogy out of the old grooves of dry description. In part iii. W. Meigen reviews recent work on the origin of dolomite, and J. J. Sederholm discusses twenty-three papers on the pre-Cambrian rocks of Fennoscandia. E. Dacqué deals with the Jurassic strata formed by transgression on the "Lemurian continent," that is, in the region between New Zealand, East Africa, and India. In part v. J. Koenigsberger discusses the earth's age, and F. Pockels the bearing of earthquake research on the nature of the earth's interior. It is clear that these reviews of geological progress, written by specialists, make the *Geologische Rundschau* a very welcome addition in all libraries of a scientific character, as well as in many private homes.

THE Geographical Pictures published by Messrs. A. and C. Black for use in schools furnish selected views of typical land features for study. Twelve of these, illustrating various forms of valleys, have just been issued in Series x. as half-tone prints of selected photographs, about 16×12 cm. Notes accompany them suggesting various problems for study. A reference to the contoured map-sheet on which the feature is represented would further enhance their educative value.

COPIES of the Tide Tables issued by the Canadian Government for the Pacific and the eastern coasts of Canada for the year 1911 have been received. For the former, tide tables are given for six stations, and from these the tides at numerous stations can be determined. The results given are largely based on the observations of 1909, when twenty recording gauges were in simultaneous operation

throughout British Columbia; besides these, however, observations for six years are available at Sand Heads station, and for shorter periods at the others. On the eastern coast longer periods are available, and the tables for Quebec are based upon observations extending over thirteen years. It is claimed that the tables for Quebec, Father Point, Halifax, and St. John are now superior to those of any other harbour on the Atlantic coast of North America.

WE have just received Water Supply Papers Nos. 245, 247, 250, 251, and 237, 239, published by the United States Geological Survey, in addition to the papers of the same series referred to elsewhere (p. 283). The first four papers deal with the surface waters of the Missouri and Lower Mississippi Basin, the Great Basin, and California, and record the gauge readings and discharge measurements made in 1907–8. Covering as they do a large area where rainfall is slight, the results are interesting, though, of course, they extend over a short period only, and are intended to be a preliminary investigation. River velocities are determined by the Price current-meter, which is almost exclusively employed by the Survey, and in this way results of much value are obtained rapidly and from a very wide area. The other two papers treat of the quality of the surface waters of Illinois and California, especially with regard to their potability and their suitability for industrial purposes.

IN the last number of the Proceedings of the Royal Society (vol. lxxxiv., A, No. 572) is an important memoir by Sir George Darwin on the tidal observations made during Sir Ernest Shackleton's Antarctic expedition of 1907. The observations are shown by Sir George Darwin to demonstrate a tidal seiche in the Ross Sea, and from its period Darwin concludes that the sea extends far beneath the Great Ice Barrier into the Antarctic continent, passing to the east of the Pole and for at least 10° of latitude beyond it. He remarks that if this arm of the sea extends across Antarctica to the Weddell Sea the seiche would be much as the tidal observations indicate. It was remarked in a note in NATURE of May 12, on the expedition by Lieut. Filchner, whose plan is based on the assumption that Antarctica is divided into two parts by a sound connecting the Ross Sea with the Weddell Sea, that if the theory be correct some evidence in its favour should have been forthcoming from the tidal observations. Sir George Darwin's memoir shows that the tides offer striking evidence in favour of the direct connection between the Weddell and Ross Seas.

AMONG several useful papers in the Journal of the Scottish Meteorological Society for 1909 (recently published) there is one of especial interest by Dr. G. A. Carse and Mr. D. MacOwan giving a brief *résumé* of the more important facts connected with atmospheric electricity. Descriptions are given of some of the earlier methods of detecting the phenomena, and of Lord Kelvin's water-dropping apparatus, which is most widely used for measuring the atmospheric potential. Observations show that, in general, this factor varies with the time (there being in most places a diurnal and annual variation), and that, generally speaking, it increases in proportion to the distance from an extended horizontal surface if the distance between the points is not too great. It has, however, been found by balloon ascents that in fine weather it diminishes with height above ground, thus indicating that electrification is largely confined to the lower levels of the atmosphere. The annual variation has a maximum about mid-winter and a minimum in summer, but the periods of the diurnal variation are much more complex. Another factor of importance is the ionisation of the atmosphere, and this is now being investigated more thoroughly. A few of the more interesting of the various theories accounting for the phenomena of atmospheric electricity are briefly sketched, but, so far as known, none has yet been promulgated which sufficiently explains all the observed facts.

To the *Rendiconti R. Accad. Lincei* of October 2 Dr. Eredia communicates an interesting paper on the cold period of June in Italy. This cold period has already been shown to exist over a large part of Europe, and to be due to the mean distribution of pressure at that period. But as Italy possesses a valuable series of observations available for the purpose, the author has taken advantage of them to show that this cold period in Italy constitutes a real climatological factor. His tables show differences of the ten-day means of temperature from each other between the third decade of May and the first decade of July, for 120 stations, for the period 1866–1906. He also gives a map showing by various shadings the difference of temperature between the first and second decades of June for different regions. These clearly show that generally there is a considerable fall of temperature in the second decade of June, that it is much more marked in Upper than in Lower Italy, and is considerably influenced by geographical configuration.

AN interesting article by Dr. J. Mascart on actinometry and on meteorology at Teneriffe is published in the *Revue générale des Sciences* of November 15. The author points out that in the determination of the solar constant a difficulty arises at the outset; according to the definition, the receiving surface should be theoretically *black for all radiations*, having the properties of an integral radiator. Strictly speaking, this preliminary problem has not yet been solved. He described the so-called "absolute" instruments in use, which may be divided into two groups:—(1) calorimetric actinometers, which contain a liquid of known specific heat, of which that by Pouillet is the oldest; (2) those in which the electric energy necessary to produce the same effect as the solar radiation is measured; to this class belong the actinometers of Ångström and Féry. The Solar Committee has adopted as a type Ångström's compensation pyrheliometer. This decision is excellent as regards uniformity of observations, but might be harmful if it diminished the number of measurements with other apparatus. Reference is made to the observations made by the late Dr. W. Marcet and others on the extreme dryness at times of the Peak of Teneriffe, and on the electric phenomena there which seem to be connected with the former. The author considers the peak to be particularly favourable for observations on atmospheric phenomena and their connection with actinometry; also for observations of terrestrial magnetism. He thinks that more attention should be given to observations of zodiacal light, crepuscular rays, and atmospheric polarisation; these subjects are generally omitted from meteorological text-books because they are supposed to have no immediate connection with meteorology, but with this view he does not agree.
